

VOLUME ONE

ENCYCLOPEDIA OF QUATERNARY SCIENCE

2ND EDITION

SCOTT A. ELIAS EDITOR-IN-CHIEF
CARY J. MOCK ASSOCIATE EDITOR

How to go to your page

This eBook is a 4 volume set.

The front matter and content of each book have their own page numbering scheme, consisting of a volume number and a page number, separated by a hyphen.

For example, to go to page 18 of Volume 1, type "I - 18" in the "page #" box at the top of the screen and click "Go."

To go to page "123" of Volume 3, type "III - 123"... and so forth.

Please refer to the eTOC for further clarification.

DEDICATIONS

The second edition of the Encyclopedia of Quaternary Science is dedicated to the memory of three outstanding scientists who have recently passed away: Russell Coope, Bill Watts, and Aleksis Dreimanis.

Russell Coope

G. Russell Coope (1930–2011) was essentially the founding father of Quaternary Entomology, having initiated the modern era of Quaternary insect fossil research in the late 1950s. Prior to that time, and going back to the nineteenth century, there had been a number of false starts and stops in this field. Previous researchers had assumed that any ice-age insect fossils they found would necessarily represent extinct taxa. This, as it turns out, was a completely false assumption. Beginning with the Late Pleistocene Upton Warren and Chelford sites, Russell was able to determine that fossil insects, especially beetles (Coleoptera) from Pleistocene deposits, represent extant species, albeit species that may live in dramatically different regions today than those where they lived in the past. For many years at the start of this endeavor, Russell was ‘a voice in the wilderness,’ having to convince colleagues in both the Quaternary sciences and modern Entomology that it is possible to identify ‘beetle bits’ (individual sclerites of beetle exoskeleton) to the species level, and that fossil beetle assemblages can yield reliable reconstructions of past environments. One of his greatest battles was to convince skeptical palynologists that the interstadial interval in what is now known as MIS 3, and another one toward the end of the last glaciation, were almost as warm as today, in spite of the fact that the vegetation cover represented in pollen records failed to register this. Likewise, Russell championed the idea that climate oscillations, particularly in the late glacial interval and early Holocene, were extremely rapid and dramatic: switching from full glacial to full interglacial conditions in a matter of decades, at most. Russell’s paleoclimate reconstructions were finally given full credence by the scientific community at large when the oxygen isotope records from Greenland ice cores began to be published, showing nearly the exact same amplitude and timing of climate change he had been publishing since the 1960s.

Russell’s research has had important implications for the field of zoogeography. On the basis of his work, we now know that insects respond to climate change chiefly by shifting their distributional ranges, so that they

Figure 1 Russell Coope at the Chelford quarry fossil site, August 1977. Photograph by Alan V. Morgan, used with permission.

track these changes through space. Through his tenacity and hard work, Russell was able to track down the modern ranges of beetle species he found in Pleistocene deposits to such remote locations as northeastern Siberia and the Tibetan Plateau (cold-adapted species), as well as North Africa and the Mediterranean islands (warm-adapted species).

Russell brought a level of curiosity and enthusiasm for natural history and all things scientific that was infectious. He was a brilliant lecturer and storyteller, holding his audiences practically spellbound. He trained many of the paleoentomologists who took the field forward in recent decades. His seemingly boundless energy kept him working and publishing papers, right up to the end of his life. He published more than 200 papers in his long career. He collaborated with dozens of other Quaternary scientists and was one of the first to appreciate and promote multidisciplinary studies of Pleistocene fossil sites. There is no doubt that his research and publishing legacies will continue to inspire future generations of paleoentomologists.

Bill Watts

William (Bill) A. Watts (1930–2010) was a towering figure in Quaternary paleoecology. He was a skilled botanist and ecologist and this was a secret to his success in unraveling the interglacial, late-glacial, and Holocene vegetation history not only in his native Ireland but also in the midwestern, the southeastern, and eastern USA, and in Italy. A major contribution was his reintroduction and development of quantitative plant macrofossil analysis. Macrofossils can often be identified to lower taxonomic levels than pollen, and Bill took full advantage of the complementarity of both methods. Thus, he was able to determine important features of vegetation history by identifying trees to species level and to illuminate the history of aquatic plants and local vegetational developments.

Figure 2 Photograph of Bill Watts, taken at Laguna de la Roya, Spain. Photograph by Fraser Mitchell, used with permission.

Bill always enjoyed fieldwork and microscope work, carrying out the latter in spare time left over from his job as Provost of Trinity College Dublin and his participation on committees dealing with hospitals and conservation in Ireland. Bill's quiet but intense enthusiasm and his great sense of humor added much to discussions, macrofossil identification sessions, and excursions with him. He and his work are inspirations to those who follow him.

Figure 3 Aleksis Dreimanis, photograph by Stephen Hicock.

Aleksis Dreimanis

Aleksis Dreimanis (1914–2011) was widely considered the world's foremost Quaternary glacial geologist in the 1970s and 80s. Aleksis was born in Latvia. While still an undergraduate at the University of Latvia, he published his first paper on the structural geology of deformed glacial deposits along the banks of the River Daugava – a study that he would return to and revise 60 years later. In 1944, Aleksis was conscripted as a military geologist by the Germans who occupied Latvia. For the next two years, he was separated from his family and forced to do strategic geological mapping in eastern Germany and northern Italy until the end of WWII, followed by internment in prisoner of war and displaced persons camps. In 1948, he escaped to London, England, where he met with the President of the University of Western Ontario who gave him a job in London, Canada (his family was able to join him the following year).

Over the next six decades at the University of Western Ontario, Aleksis ascended to the top of his discipline while gaining international recognition through landmark publications and inspired leadership on committees. His 1970s synthesis and definition of the Wisconsin Stage with Paul Karrow, Jan Terasmae, Dick Goldthwait, and Jane Forsyth became a world standard to which other records were compared. In 1989, he expanded this synthesis and introduced the conceptual till tetrahedron that showed the till continuum with end members occupying the corners of an inverted pyramid. He was among the first geologists to use radiocarbon dating, and he provided samples for inter-lab calibration. He was among the first to quantitatively study the relationship between till lithology and till formation, and to investigate how glacial transport and dynamics determine till texture, deformation, and rheologic states. Aleksis produced over 200 publications spanning eight decades and over a wide range of topics. Largely because of his influence, the study of till genesis and its relation to till properties and past glacial behavior has become a major focus of glacial geologic research in recent decades. The contribution and legacy that forms the body of work of Dreimanis will continue as a major benchmark within the diverse fields of scientific enquiry that are sometimes loosely referred to as 'glacial geology.'

FOREWORD

As with the publication of the first edition in 2007, the publication of the second edition of the *Encyclopedia of Quaternary Science* represents a landmark in the history of publishing in the field of Quaternary Science. Quaternary Science is a multidisciplinary endeavor which seeks to establish as detailed a picture as possible of the manifold environmental changes that have occurred during the most recent geological period, the Quaternary – an interval of time that spans the past 2.59 million years or the past 0.056% of geological time. It is a period of significant climate and environmental change and witnessed the widespread dispersal of our species, *Homo sapiens*, across the planet.

Since Louis Agassiz and Reverend William Buckland traipsed over parts of the Scottish landscape in 1840 in search of evidence of glaciation, a huge literature has emerged on the science of long-term climate and environmental change. Rapid technological advances in the late twentieth century and the proliferation of scientific journals, particularly in an era of electronic publishing, have resulted in an exponential growth and documentation of knowledge on the climate and environmental changes that have occurred during the Quaternary period. More recently, there has been an increasing public interest in applied Quaternary research as a framework for understanding the basis for recent climate changes and for understanding the nature and frequency of geological hazards and vexing issues such as soil erosion and land degradation, and the adverse effects of ocean water temperature increases and acidification on coral reef environments. In a similar manner, the likely magnitude of future sea-level rise and the associated impacts on coastal landscapes in the twenty-first century have attracted wide public interest. In this sense, Quaternary Science is very much on the political agenda and is a critically important subject to address issues of public concern.

The *Encyclopedia of Quaternary Science* edited by Scott Elias of Royal Holloway, University of London, UK, accordingly represents a particularly welcome addition to the literature. The encyclopedia presents an up-to-date and authoritative overview of Quaternary Science. The encyclopedia should enjoy a wide readership as the entries are presented in a very clear and easily readable style. The text of the articles is written at a level that allows undergraduate students to understand the material, while providing active researchers with a ready reference resource for information in the field. Each entry of up to 4000 words covers the salient points of each topic with very clear illustrations. A central theme that pervades the work is the importance of Quaternary Science in providing an historical context for assessing present environmental changes and as basis for modeling potential future changes.

The encyclopedia consists of four volumes in print form and is available electronically. All the entries have been updated and the text totals around 3,500,000 words. As a major reference work, the encyclopedia has a very wide coverage of topics within the Quaternary sciences reflecting the complex and interdisciplinary nature of the science. Each of the major sections begins with a general overview of the topic prepared by a leading expert in the field. The major sections, for example, examine the analytical methods commonly used in paleoenvironmental reconstructions to unravel in a forensic-like manner the nature of former environments and the tempo of environmental change. Accordingly, a great range of topics such as the former extent of ice cover and nature of Quaternary glaciations, the biological responses and resultant fossil records to fluctuating climate, the expansion and contraction of desert environments, and global and local changes in relative sea levels are examined. Other topics covered include dating techniques, Quaternary stratigraphy, fluvial environments, lake level studies, paleosols, paleobotany, ancient DNA, paleolimnology, vertebrate studies, insect fossil studies, paleoceanography, stable isotope studies, ice core records, and human evolution in the Quaternary. One of the new sections in the encyclopedia examines the application of Quaternary proxy evidence in forensic science. All sections provide a clear summary of the latest advances in the fields of research.

This is an outstanding work and the editors and the publisher are to be congratulated for producing an encyclopedia that cogently summarizes the current state of the science.

INTRODUCTION

It has been my privilege to work with more than 420 leading Quaternary scientists in developing the second edition of the *Encyclopedia of Quaternary Science*. This team of writers and editors represents 28 countries in Europe, Asia, Africa, the Americas, Australia, and New Zealand. Starting with the first edition in 2006, I have had my finger on the pulse of Quaternary science, and this branch of science is truly pulsating! Information now comes from an incredible variety of disciplines: geochemistry, numerical modeling, history, vulcanology, paleobiology, nuclear physics, stratigraphy, sedimentology, climatology, anthropology, archaeology, glacial geology, soil science, ice-stream modeling – the list is staggering. This highly disparate group of people are bound together by one common thread: the desire to know the history of the planet during the last 2.6 million years – the time of the ice ages. For Quaternary scientists, this is a pressing need, not an idle curiosity. Any doubts about this statement can be easily dispelled by a consideration of the lengths to which many of them go to gather the necessary data. Some of them have worked for months in sub-zero temperatures on top of very high mountains, or near the center of polar ice sheets, collecting ice cores. Others have spent many weeks on some of the roughest seas in the world, drilling deep-sea sediment cores. Often the work is more mundane. An oxygen isotope curve for a lengthy marine sediment core represents thousands of hours of patiently picking tiny fossils from layer after layer of sediments, in order to obtain sufficient numbers of calcium carbonate shells to yield samples for isotopic analysis. A map showing proposed ice limits from the last glaciation represents thousands of hours of field mapping of glacial features by dozens of people. Why do all of these people devote their lives to this pursuit of knowledge? Does it really matter so much? The answer becomes clear when you step back and examine the topic of Quaternary science in its proper context.

The world we inhabit has largely been shaped by the events of the Quaternary. All the biological communities that exist today are the end product of a long series of species associations that came together in the past, largely driven by climatic change during the Pleistocene. We cannot properly understand the functioning of modern ecosystems without a solid knowledge of their history, any more than we can understand the plot of a long novel by reading just the final page. We are also living in a time of alarming climate changes. Even though the pace and intensity of some of these changes have not been seen in historical times, there were many rapid, large-scale climatic shifts in the Pleistocene. The best way to predict the effects of global warming on the planet's climate and ecosystems is to look at the history of similarly intense, rapid changes in the prehistoric past. The interval that is most relevant today is the most recent geologic period: the Quaternary. As human populations rise exponentially, increasing numbers of people are exposed to geologic hazards, such as earthquakes (and attendant tsunamis), and volcanic eruptions. These are short-lived events that take place only rarely in any one region. The interval between major events, such as volcanic eruptions, may be centuries or millennia. How do we come to grips with predicting the future likelihood of such erratic phenomena? Again, the answers come from piecing together the ancient history of such events, over many thousands of years.

The Quaternary has been the time when our own species came of age. The beginning of the Quaternary, roughly 2.6 million years ago, was about the time when the earliest member of our genus (*Homo*) first appeared in Africa. Pleistocene environments shaped the course of human evolution, culminating in anatomically modern *Homo sapiens* spreading from Africa throughout most of the world during the last glaciation. Even though human beings largely shape their own environments today, for the vast majority of our species' history, it has been the environment that has shaped us. Our direct ancestors' adaptations to environmental change are deeply ingrained in our genes. Thus, an understanding of the environmental conditions that shaped our species is critical to our understanding of humanity.

Quaternary science is a rapidly changing field, and the articles that appear in this encyclopedia reflect this. New dating techniques, such as cosmogenic nuclide dating, are revolutionizing our understanding of many earth surface processes. The ability to analyze increasingly smaller samples for radiocarbon and stable isotopes of oxygen and hydrogen means that we are gaining a level of precision in the reconstruction of past events that was unheard of just a few years ago. Stable isotope studies of air bubbles trapped in ice cores from Greenland and Antarctica have given Quaternary scientists an entirely new perspective on the rapidity and intensity of climatic change during the last glacial cycle and beyond. Likewise, the discovery of long sequences of annually laminated sediments in both marine and freshwater environments has provided a great leap forward in our ability to resolve the timing of environmental changes in nonpolar regions. The ability to extract and analyze ancient DNA sequences from Pleistocene fossils (both plants and animals) is revolutionizing the field of paleobiology. We are beginning to be able to trace the genetic lineages of a number of different organisms, from beetles to bison. In short, these are very exciting times to be a Quaternary scientist! While it is virtually impossible for any Quaternary researcher or student to keep abreast of all the new discoveries in this multifaceted science, this encyclopedia can be of great help. The articles contained here represent the state of the art in a huge variety of topics, and they offer the opportunity to dig deeper into their respective subjects by providing full citations of the most pertinent literature available. I invite you to come and explore the Quaternary Period in the pages that follow. It is a fascinating story.

HOW TO USE THE ENCYCLOPEDIA

The material in this encyclopedia is organized into two broad sections. At the start of Volume 1 are four *Introductory Articles* that serve as a broad introduction to the field. It is intended that these articles should serve as the first port of call for readers, to enable them to embark on any of the main entries without the need to consult other material beforehand.

Following the Introductory Articles, the main body of The Encyclopedia is arranged as a series of entries in alphabetical order. These entries fill the remainder of the volumes.

To help realize the full potential of the material in the Encyclopedia we have provided four features to help you find the topic of your choice: a contents list by subject; an alphabetical contents list; cross-references to other articles; and a full subject index.

1. Contents list by subject

Your first point of reference will probably be the contents list by subject. This list appears at the front of each volume, and groups the entries under subject headings describing the broad themes of Quaternary science. This will enable the reader to make quick connections between entries and to locate the entry of interest. Under each main section heading, you will find several subject areas and under each subject area is a list of those entries that covers aspects of that subject, together with the volume and page numbers on which these entries may be found.

2. Alphabetical contents list

The alphabetical contents list, which also appears at the front of each volume, lists the entries in the order in which they appear in the Encyclopedia. This list provides both the volume number and the page number of each entry.

You will find ‘dummy’ entries where obvious synonyms exist for entries or where we have grouped together related topics. Dummy entries appear in both the contents list and the body of the text.

Example

If you were attempting to locate material on *peat studies* via the alphabetical contents list:

PEAT STUDIES *see* PLANT MACROFOSSIL METHODS AND STUDIES: Mire and Peat Macros

The dummy entry directs you to the entry in which *peat* is covered.

If you were trying to locate the material by browsing through the text and you had looked up *Peat Studies*, then the following information would be provided in the dummy entry:

Peat Studies *see* PLANT MACROFOSSIL METHODS AND STUDIES: Mire and Peat Macros

3. Cross-references

All of the entries in the Encyclopedia have been extensively cross-referenced. The cross-references, which appear at the end of the entry, serve three different functions:

- i. To indicate if a topic is discussed in greater detail elsewhere.
- ii. To draw the reader’s attention to parallel discussions in other entries.
- iii. To indicate material that broadens the discussion.

Example

The following list of cross-references appear at the end of the entry GLACIAL LANDFORMS, ICE SHEETS | Growth and Decay

See also: **Introduction:** History of Quaternary Science; **Paleoclimate Reconstruction:** Sub-Milankovitch (DO/Heinrich) Events; **Glacial Climates:** Thermohaline Circulation; **Glaciation, Causes:** Astronomical Theory of Paleoclimates; **Paleoclimate Modeling:** Last Glacial Maximum GCMs; **Glaciations:** Overview; **Sea Level Studies:** Overview; Paleocceanography; **Ice Core Records:** Correlations Between Greenland and Antarctica.

Here you will find examples of all three functions of the cross-reference list: a topic discussed in greater detail elsewhere (e.g., **Paleoclimate Modeling:** Last Glacial Maximum GCMs), parallel discussion in other entries (e.g., **Glacial Climates:** Thermohaline Circulation), and reference to entries that broaden the discussion (e.g., **Glaciations:** Overview).

4. Index

The index provides you with the page number where the material is located. The index entries differentiate between material that is a whole entry, is part of an entry, or is data presented in a figure or a table. Detailed notes are provided on the opening page of the index.

5. Contributors

A full list of contributors is listed at the beginning of each volume.

CONTENTS LIST BY SUBJECT

Location references refer to the volume number and page number (separated by a colon)

Introduction and History of Science

INTRODUCTION | History of Quaternary Science, 1:1
INTRODUCTION | History of Dating Methods, 1:9
INTRODUCTION | Societal Relevance of Quaternary Research, 1:17

 PERMAFROST AND PERIGLACIAL FEATURES | Yedoma: Late Pleistocene Ice-Rich Syngenetic Permafrost of Beringia, 3:542

Tree-ring section

DENDROCHRONOLOGY, 1:453
 DENDROCLIMATOLOGY, 1:459
 GLACIAL LANDFORMS, TREE RINGS | Dendrogeomorphology, 2:91
 GLACIAL LANDFORMS, TREE RINGS | Dendroglaciology, 2:104

Fluvial Environments

FLUVIAL ENVIRONMENTS | Sediments, 1:663
 FLUVIAL ENVIRONMENTS | Terrace Sequences, 1:684
 Glacial–Interglacial Scale Fluvial Responses, 2:112
 FLUVIAL ENVIRONMENTS | Responses to Rapid Environmental Change, 1:676
 FLUVIAL ENVIRONMENTS | Deltaic Environments, 1:693
 PALEOHYDROLOGY, 3:253

History of Quaternary Glaciations

GLACIATIONS | Overview, 2:143
 GLACIATIONS | Transition from Late Neogene to Early Quaternary Environments, 2:151
 GLACIATIONS | Early Quaternary (Pleistocene) and Precursors, 2:167
 GLACIATIONS | Middle Pleistocene in Eurasia, 2:172
 GLACIATIONS | Mid-Quaternary in North America, 2:180
 GLACIATIONS | Middle Pleistocene Glaciations in the Southern Hemisphere, 2:187
 GLACIATIONS | Late Quaternary of Antarctica, 2:216
 GLACIATIONS | Late Quaternary in North America, 2:245
 GLACIATIONS | Late Quaternary in Highland Asia, 2:236
 GLACIATIONS | Late Quaternary of the Southwest Pacific Region, 2:202
 GLACIATIONS | Late Pleistocene in Eurasia, 2:224
 GLACIATIONS | Late Pleistocene in South America, 2:250
 GLACIATIONS | Late Pleistocene Glacial Events in Beringia, 2:191
 GLACIATIONS | Neoglaciation in Europe, 2:257
 GLACIATIONS | Neoglaciation in the American Cordilleras, 2:269

Sea Level Studies

SEA LEVEL STUDIES | Overview, 4:369
 SEA LEVEL STUDIES | Geomorphological Indicators, 4:377
 SEA LEVEL STUDIES | Coral Records of Relative Sea-Level Changes, 4:409
 SEA LEVEL STUDIES | Use of Cave Data in Sea-Level Reconstructions, 4:460
 SEA LEVEL STUDIES | Eustatic Sea-Level Changes – Glacial–Interglacial Cycles, 4:429
 SEA LEVEL STUDIES | Eustatic Sea-Level Changes Since the Last Glacial Maximum, 4:439

SEA LEVEL STUDIES | Isostasy: Glaciation-Induced Sea-Level Change, 4:452
SEA LEVEL STUDIES | Sedimentary Indicators of Relative Sea-Level Changes – High Energy, 4:385
SEA LEVEL STUDIES | Sedimentary Indicators of Relative Sea-Level Changes – Low Energy, 4:396
SEA LEVEL STUDIES | Microfossil-Based Reconstructions of Holocene Relative Sea-Level Change, 4:419
SEA-LEVELS, LATE QUATERNARY | Late Quaternary Relative Sea-Level Changes in High Latitudes, 4:467
SEA-LEVELS, LATE QUATERNARY | Late Quaternary Sea-Level Changes in Greenland, 4:481
SEA-LEVELS, LATE QUATERNARY | Late Quaternary Relative Sea-Level Changes at Mid-Latitudes, 4:489
SEA-LEVELS, LATE QUATERNARY | Late Quaternary Relative Sea-Level Changes in the Tropics, 4:495
SEA-LEVELS, LATE QUATERNARY | Tectonics and Relative Sea-Level Change, 4:503

Paleosols and Wind-Blown Sediments

Paleosol Research

PALEOSOLS AND WIND-BLOWN SEDIMENTS | Overview, 3:357
PALEOSOLS AND WIND-BLOWN SEDIMENTS | Nature of Paleosols, 3:367
LOESS DEPOSITS: ORIGINS AND PROPERTIES, 2:573
PALEOSOLS AND WIND-BLOWN SEDIMENTS | Weathering Profiles, 3:392
PALEOSOLS AND WIND-BLOWN SEDIMENTS | Soil Micromorphology, 3:381
PALEOSOLS AND WIND-BLOWN SEDIMENTS | Soil Morphology in Quaternary Studies, 3:402
PALEOSOLS AND WIND-BLOWN SEDIMENTS | Mineral Magnetic Analysis, 3:375
PALEOSOLS AND WIND-BLOWN SEDIMENTS | Biogeochemical Role of Dust in Quaternary Climate Cycles, 3:412

Dune Studies

DUNE FIELDS | High Latitudes, 1:597
DUNE FIELDS | Mid-Latitudes, 1:606
DUNE FIELDS | Low Latitudes, 1:623

Loess Studies

LOESS RECORDS | Central Asia, 2:585
LOESS RECORDS | China, 2:595
LOESS RECORDS | Europe, 2:606
LOESS RECORDS | North America, 2:620
LOESS RECORDS | South America, 2:629
EOLIAN RECORDS, DEEP-SEA SEDIMENTS, 1:637

Lake Level Studies

LAKE LEVEL STUDIES | Overview, 2:483
LAKE LEVEL STUDIES | Modeling, 2:558
LAKE LEVEL STUDIES | Africa during the Late Quaternary, 2:499
LAKE LEVEL STUDIES | Asia, 2:506
LAKE LEVEL STUDIES | Australia, 2:524
LAKE LEVEL STUDIES | Latin America, 2:531
LAKE LEVEL STUDIES | North America, 2:537
LAKE LEVEL STUDIES | West-Central-Europe, 2:549

Paleobotany

Overview

PALEOBOTANY | Overview of Terrestrial Pollen Data, 2:699

Pollen Studies

POLLEN ANALYSIS, PRINCIPLES, 3:794
POLLEN METHODS AND STUDIES | Use of Pollen as Climate Proxies, 3:805
POLLEN METHODS AND STUDIES | Surface Samples and Trapping, 3:839
POLLEN METHODS AND STUDIES | The Biome Approach to Reconstructing Past Vegetation, 3:861
POLLEN METHODS AND STUDIES | POLLSCAPE Model, 3:871
POLLEN METHODS AND STUDIES | Reconstructing Past Biodiversity Development, 3:816
POLLEN METHODS AND STUDIES | Numerical Analysis Methods, 3:821
POLLEN METHODS AND STUDIES | Changing Plant Distributions and Abundances, 3:854
POLLEN METHODS AND STUDIES | Stand-Scale Palynology, 3:846
PALEOBOTANY | Paleophytogeography, 2:730
POLLEN METHODS AND STUDIES | Databases and Their Application, 3:831

Charred Particle Analysis

PALEOBOTANY | Charred Particle Analyses, 2:716

Quaternary Pollen Records

POLLEN RECORDS, LAST INTERGLACIAL OF EUROPE, 4:1
POLLEN RECORDS, LATE PLEISTOCENE | Africa, 4:9
POLLEN RECORDS, LATE PLEISTOCENE | Australasia, 4:18
POLLEN RECORDS, LATE PLEISTOCENE | Northern Asia, 4:27

POLLEN RECORDS, LATE PLEISTOCENE | Northern North America, 4:39
 POLLEN RECORDS, LATE PLEISTOCENE | Western North America, 4:72
 POLLEN RECORDS, LATE PLEISTOCENE | South America, 4:52
 POLLEN RECORDS, LATE PLEISTOCENE | Middle and Late Pleistocene in Southern Europe, 4:63
 POLLEN RECORDS, POSTGLACIAL | Africa, 4:85
 POLLEN RECORDS, POSTGLACIAL | Australia and New Zealand, 4:104
 POLLEN RECORDS, POSTGLACIAL | Northeastern North America, 4:115
 POLLEN RECORDS, POSTGLACIAL | Northwestern North America, 4:124
 POLLEN RECORDS, POSTGLACIAL | Southeastern North America, 4:133
 POLLEN RECORDS, POSTGLACIAL | Southwestern North America, 4:142
 POLLEN RECORDS, POSTGLACIAL | South America, 4:156
 POLLEN RECORDS, POSTGLACIAL | Northern Asia, 4:164
 POLLEN RECORDS, POSTGLACIAL | Northern Europe, 4:173
 POLLEN RECORDS, POSTGLACIAL | Southern Europe, 4:179
 POLLEN METHODS AND STUDIES | Archaeological Applications, 3:880

Phytoliths

PHYTOLITHS, 3:582

Ancient Plant DNA

PALEOBOTANY | Ancient Plant DNA, 2:705

Plant Macrofossil Studies

PLANT MACROFOSSIL INTRODUCTION, 3:593
 PLANT MACROFOSSIL METHODS AND STUDIES | Surface Samples, Taphonomy, Representation, 3:684
 PLANT MACROFOSSIL METHODS AND STUDIES | Treeline Studies, 3:690
 PLANT MACROFOSSIL METHODS AND STUDIES | Megafossils, 3:621
 PLANT MACROFOSSIL METHODS AND STUDIES | Paleolimnological Applications, 3:657
 PLANT MACROFOSSIL METHODS AND STUDIES | CO₂ Reconstruction from Fossil Leaves, 3:613
 PLANT MACROFOSSIL METHODS AND STUDIES | Rodent Middens, 3:674

PLANT MACROFOSSIL METHODS AND STUDIES | Mire and Peat Macros, 3:637
 PLANT MACROFOSSIL METHODS AND STUDIES | Use in Environmental Archaeology, 3:699
 PLANT MACROFOSSIL METHODS AND STUDIES | Dendroarchaeology, 3:630
 PLANT MACROFOSSIL METHODS AND STUDIES | Validation of Pollen Studies, 3:725

Plant Macrofossil Records

PLANT MACROFOSSIL RECORDS | Arctic Eurasia, 3:733
 PLANT MACROFOSSIL RECORDS | Greenland, 3:760
 PLANT MACROFOSSIL RECORDS | Arctic North America, 3:746
 PLANT MACROFOSSIL RECORDS | Holocene North America, 3:768
 PLANT MACROFOSSIL RECORDS | Late Glacial Multidisciplinary Studies, 3:785

Diatom Studies

DIATOM INTRODUCTION, 1:471
 DIATOM METHODS | Data Interpretation, 1:489
 DIATOM RECORDS | North Atlantic and Arctic, 1:562
 DIATOM RECORDS | Pacific, 1:571
 DIATOM RECORDS | Antarctic Waters, 1:527
 DIATOM RECORDS | Diatom Fossil Records from Marine Laminated Sediments, 1:554
 DIATOM RECORDS | Freshwater Laminated Sequences, 1:540
 DIATOM RECORDS | Large Lakes, 1:546
 DIATOM METHODS | Salinity and Climate Reconstructions from Continental Lakes, 1:507
 DIATOM METHODS | $\delta^{18}\text{O}$ Records, 1:481
 PALEOBOTANY | Silicon Isotopes in Diatoms, 2:734
 DIATOM METHODS | Use in Archaeology, 1:516
 DIATOM METHODS | Diatomites: Their Formation, Distribution, and Uses, 1:501
 Structures and Applications of Biomarkers from Arctic Sea Ice Diatoms, 1:588

Paleolimnology

PALEOLIMNOLOGY | Overview of Paleolimnology, 3:259
 PALEOLIMNOLOGY | Lake Chemistry, 3:292
 PALEOLIMNOLOGY | Physical Properties of Lake Sediments, 3:300
 PALEOLIMNOLOGY | Cladocera, 3:271
 PALEOLIMNOLOGY | Freshwater Mollusks, 3:281

PALEOLIMNOLOGY | Contributions of
Paleolimnological Research to
Biogeography, 3:313
PALEOLIMNOLOGY | Pigment Studies, 3:326
PALEOLIMNOLOGY | Visible and Infrared
Spectroscopical Applications, 3:349
PALEOLIMNOLOGY | Multiproxy Approaches, 3:339

Vertebrate Studies

VERTEBRATE OVERVIEW, 4:590
VERTEBRATE RECORDS | Early Pleistocene, 4:599
VERTEBRATE RECORDS | Early and Middle
Pleistocene of Northern Eurasia, 4:605
VERTEBRATE RECORDS | Mid-Pleistocene of
Southern Asia, 4:651
VERTEBRATE RECORDS | Mid-Pleistocene of
Africa, 4:615
VERTEBRATE RECORDS | Mid-Pleistocene of
Australia, 4:621
VERTEBRATE RECORDS | Mid-Pleistocene of
Europe, 4:639
VERTEBRATE RECORDS | Mid-Pleistocene of
North America, 4:646
VERTEBRATE RECORDS | Late Pleistocene of
Africa, 4:664
VERTEBRATE RECORDS | Late Pleistocene of North
America, 4:673
VERTEBRATE RECORDS | Late Pleistocene of South
America, 4:680
VERTEBRATE RECORDS | Late Pleistocene of
Southeast Asia, 4:693
VERTEBRATE RECORDS | Late Pleistocene
Megafaunal Extinctions, 4:700
VERTEBRATE RECORDS | Late Pleistocene
Mummified Mammals, 4:713
VERTEBRATE STUDIES | Ancient DNA, 4:719
VERTEBRATE STUDIES | Speciation and
Evolutionary Trends in Quaternary
Vertebrates, 4:723
VERTEBRATE STUDIES | Dwarfing and Gigantism in
Quaternary Vertebrates, 4:733
VERTEBRATE STUDIES | Interactions with
Hominids, 4:748

Insect Fossil Studies

Beetle Studies

BEETLE RECORDS | Overview, 1:161
BEETLE RECORDS | Late Tertiary and Early
Quaternary Records, 1:173
BEETLE RECORDS | Middle Pleistocene of Western
Europe, 1:184

BEETLE RECORDS | Late Pleistocene of
Europe, 1:200
BEETLE RECORDS | Late Pleistocene of North
America, 1:221
BEETLE RECORDS | Late Pleistocene of South
America, 1:235
BEETLE RECORDS | Late Pleistocene of
Australia, 1:191
BEETLE RECORDS | Late Pleistocene of Northern
Asia, 1:255
BEETLE RECORDS | Late Pleistocene of Japan, 1:207
BEETLE RECORDS | Late Pleistocene of New
Zealand, 1:244
BEETLE RECORDS | Postglacial Europe, 1:274
BEETLE RECORDS | Postglacial North America, 1:282

Chironomid Studies

CHIRONOMID RECORDS | Chironomid
Overview, 1:355
CHIRONOMID RECORDS | Late Pleistocene of
Europe, 1:373
CHIRONOMID RECORDS | Africa, 1:361
CHIRONOMID RECORDS | Late Pleistocene of
Europe, 1:373
CHIRONOMID RECORDS | Postglacial
Europe, 1:386
CHIRONOMID RECORDS | Postglacial Southern
Hemisphere, 1:398

Oribatid Mite Studies

ORIBATID MITES, 2:680

Paleoceanography

Paleoceanographic Studies

PALEOCEANOGRAPHY | Paleoceanography An
Overview, 2:745
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Corals, Sclerosponges and Mollusks, 2:795
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Benthic Foraminifera, 2:765
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Planktic Foraminifera, 2:825
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Radiolarians and Silicoflagellates, 2:830
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Coccolithophores, 2:783
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Alkenone Paleothermometry Based on the
Haptophyte Algae, 2:755
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Marine Diatoms, 2:816

PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Dinoflagellates, 2:800

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Terrigenous
Sediments, 2:941

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Oxygen Isotopic
Composition of Seawater, 2:915

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Oxygen-Isotope
Stratigraphy of the Oceans, 2:907

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Dissolution of Deep-Sea
Carbonates, 2:859

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Mg/Ca and Sr/Ca
Paleothermometry from Calcareous Marine
Fossils, 2:871

PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Temperature Proxies Census Counts, 2:841

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Salinity Proxies
 $\delta^{18}\text{O}$, 2:932

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Nutrient Proxies, 2:899

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Carbon Cycle
Proxies, 2:849

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Radioisotope
Proxies, 2:923

PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Biomarkers Indicators of Past Climate, 2:775

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Magnetic Proxies and
Susceptibility, 2:884

Paleoceanographic Records

PALEOCEANOGRAPHY, RECORDS | Early
Pleistocene, 3:1

PALEOCEANOGRAPHY, RECORDS | Late
Pleistocene North Atlantic, 3:9

PALEOCEANOGRAPHY, RECORDS | Late
Pleistocene South Atlantic, 3:18

PALEOCEANOGRAPHY, RECORDS | Late
Pleistocene North Pacific, 3:33

PALEOCEANOGRAPHY, RECORDS | Postglacial
North Atlantic, 3:55

PALEOCEANOGRAPHY, RECORDS | Postglacial
North Pacific, 3:62

PALEOCEANOGRAPHY, RECORDS | Postglacial
South Pacific, 3:73

PALEOCEANOGRAPHY, RECORDS | Postglacial
Indian Ocean, 3:46

Ice Core Studies

Ice Core Studies

ICE CORE METHODS | Overview, 2:278

ICE CORES | History of Research, Greenland and
Antarctica, 2:435

ICE CORE METHODS | Chronologies, 2:303

ICE CORE METHODS | Stable Isotopes, 2:347

ICE CORE METHODS | Conductivity Studies, 2:319

ICE CORE METHODS | Glaciochemistry, 2:326

ICE CORE METHODS | Biological Material, 2:288

ICE CORE METHODS | Microparticle and Trace
Element Studies, 2:342

ICE CORE METHODS | CO_2 Studies, 2:311

ICE CORE METHODS | Methane Studies, 2:334

ICE CORE METHODS | ^{10}Be and Cosmogenic
Radionuclides in Ice Cores, 2:353

ICE CORE METHODS | Studies of Firn Air, 2:361

Ice Core Records

ICE CORES | History of Carbon Monoxide and
Ultra-Trace Gases from Ice Cores, 2:463

ICE CORES | History of Nitrous Oxide from Ice
Cores, 2:471

ICE CORES | Dynamics of the Greenland Ice
Sheet, 2:439

ICE CORES | Dynamics of the East Antarctic Ice
Sheet, 2:456

ICE CORES | Dynamics of the West Antarctic Ice
Sheet, 2:448

ICE CORE METHODS | Borehole Temperature
Records, 2:298

ICE CORE RECORDS | Greenland Stable
Isotopes, 2:403

ICE CORE RECORDS | Antarctic Stable Isotopes, 2:395

ICE CORE RECORDS | Ice Margin Sites, 2:416

ICE CORE RECORDS | Correlations Between
Greenland and Antarctica, 2:410

ICE CORE RECORDS | Africa, 2:373

ICE CORE RECORDS | Chinese, Tibetan
Mountains, 2:379

ICE CORE RECORDS | South America, 2:387

ICE CORE RECORDS | Thermal Diffusion
Paleotemperature Records, 2:431

Stable Isotope Research – Carbonates

CARBONATE STABLE ISOTOPES | Overview, 1:291

CARBONATE STABLE ISOTOPES |
Speleothems, 1:294

CARBONATE STABLE ISOTOPES | Terrestrial Teeth
and Bones, 1:304

CARBONATE STABLE ISOTOPES | Terrestrial
Organic Materials, 1:315
CARBONATE STABLE ISOTOPES | Non-Lacustrine
Terrestrial Studies, 1:322
CARBONATE STABLE ISOTOPES | Lake
Sediments, 1:333
CARBONATE STABLE ISOTOPES | Nonmarine
Biogenic Carbonates, 1:341

Humans in the Quaternary

ARCHAEOLOGICAL RECORDS | Overview, 1:49
ARCHAEOLOGICAL RECORDS | 2.7 Myr–300 000
Years Ago in Africa, 1:59
ARCHAEOLOGICAL RECORDS | 2.7 Myr–300 000
Years Ago in Asia, 1:67
ARCHAEOLOGICAL RECORDS | 1.9 Myr–300 000
Years Ago in Europe, 1:83
ARCHAEOLOGICAL RECORDS | Global Expansion
300 000–8000 Years Ago, Africa, 1:91
ARCHAEOLOGICAL RECORDS | Global Expansion

Introduction

The Quaternary sciences represent the systematic study of the Quaternary or the most recent geologic period. This period is generally characterized by a series of glaciations, or Ice Ages, interspersed with relatively warm, interglacial intervals, such as the current interglacial, the Holocene. The study of Quaternary environments began in the late eighteenth century. Quaternary geology and paleontology came of age in the nineteenth century, and other important aspects of Quaternary science, such as paleoceanography, paleoecology, and paleoclimatology, developed to a much greater extent in the twentieth century. As with many branches of science, the pioneers in Quaternary studies had to work hard to overcome many widely held, erroneous ideas from previous generations of scholars.

At the beginning of the nineteenth century, science itself was rapidly changing. Up until that time, university professors and other scholars who performed scientific research had mostly been generalists who dabbled in many different fields. They looked upon themselves as natural historians, studying the workings of the natural world as their whimsy led them. The early nineteenth century saw the beginnings of specialization in science. As the level of scientific knowledge was rapidly increasing, it was no longer possible for individual scholars to keep abreast of all the new discoveries. People began to devote their time and energy to one or just a few lines of research. This new, focused style of scientific study brought great leaps forward for science as a whole, and for Quaternary science in particular, as we shall see in this article.

Establishing the Geologic Framework

The term 'Quaternary' was coined by an Italian mining engineer, Giovanni Arduino (1714–95). He distinguished four

orders of strata comprising all of Earth's history: Primary, Secondary, Tertiary, and Quaternary (Schneer, 1969: 10). Arduino (Figure 1) distinguished four separate stages or 'orders,' which he recognized on the basis of very large strata arranged one above the other.

These four 'orders' were expressed regionally in Italy, as the Atesine Alps, the Alpine foothills, the sub-Alpine hills, and the Po River plain, respectively. The term 'Quaternary' apparently was not used again until the French geologist, Desnoyers (1829), used it to differentiate Tertiary from Younger strata in the Paris basin. It was redefined by another Frenchman, Reboul (1833), to include all strata containing extant flora and fauna.

The Quaternary period, as we now know it, is divided into two epochs: the Pleistocene and the Holocene. The history of these terms is likewise complicated. The term 'Pleistocene' was coined by Scottish geologist, Charles Lyell (1839; Figure 2), to replace his previous term 'Newer Pliocene' (1833).

Lyell defined the Pleistocene as the 'most recent' geologic era and further specified that Pleistocene rocks and sediments are characterized by their fossil content of 90% mollusks that are recognized as living species. As glacial theory began to take shape (see below), Forbes (1846) redefined the Pleistocene as equivalent to the 'Glacial Epoch.' Then, Hörnes (1853) introduced the term 'Neogene' to include Lyell's Miocene and Pliocene. In response, Lyell (1873) specified that the term Pleistocene should be used 'as strictly synonymous with post-Pliocene.' In the same publication, Lyell also separated the Pleistocene (glacial) from the 'Recent' (postglacial) time. The term 'Recent' was later replaced by the term 'Holocene' by Gervais (1867–69).

Thus, by the end of the nineteenth century, the stratigraphic nomenclature of the Quaternary period had been firmly established. However, no one knew when the Tertiary ended and the Quaternary began. In geology, it is standard procedure to

Figure 1 Giovanni Arduino (1714–95).

Figure 2 Charles Lyell (1797–1875).

designate a type locality that typifies the boundaries between major stratigraphic units. The 18th International Geological Congress (London, 1948) resolved to select a type locality for the Pliocene–Pleistocene (Tertiary–Quaternary) boundary. After three decades of deliberations, the Vrica section in Calabria, southern Italy, was finally selected. Hence, the Plio–Pleistocene boundary was established at this site, where the boundary falls at approximately 1.64 Ma (Aguirre and Pasini, 1985; Bassett, 1985). Hilgen (1991) calibrated this age, on the basis of an orbital forcing chronology, to an age of 1.81 Ma. These age designations were made possible only through the invention of radiometric dating methods, which came about in the latter half of the twentieth century (see below).

The Discovery of Pleistocene Mammals

The threads of research that eventually led to modern Quaternary science came from a variety of disciplines and were driven

Figure 3 Georges Cuvier (1769–1832).

by scientific observations in a number of fields. One of these was the field of vertebrate paleontology. As with many branches of science, pivotal discoveries often launch major lines of research. One such discovery was made at a Pleistocene site in Kentucky, called Big Bone Lick. The site lies on a tributary of the Ohio River, about 30 km southwest of Cincinnati, Ohio. It was the first major New World fossil locality known to Europeans. Baron Charles de Lougueuil, the commander of a French military expedition, may have been the first European to visit the site in 1739. He collected some mastodon fossils that were later studied by the French naturalists, Daubenton, Buffon, and Cuvier. Cuvier (1825) published a description of the Big Bone Lick mastodon remains. Inspired by this and other Pleistocene fossil discoveries, Cuvier developed his theory of global cooling that led to the extinction of these strange beasts.

In 1807, at the behest of Thomas Jefferson, William Clark conducted a major collecting expedition at Big Bone Lick that yielded about 300 specimens, most of which can still be found at either the National Museum of Natural History in Paris or the Academy of Natural Sciences in Philadelphia. Thus, the fossils from this one site helped to launch Pleistocene vertebrate paleontology in two continents. The discovery of mastodon and other large Pleistocene mammal remains at this site sparked the imagination of scientists and politicians alike. In 1803, the United States purchased the Louisiana Territory from France. This territory included more than 2 million square kilometers of land extending from the Mississippi River to the Rocky Mountains. When President Thomas Jefferson sent Meriwether Lewis and William Clark to explore and map this new American territory, he expected that they might find living specimens of mastodon and other large Pleistocene mammals roaming the uncharted wilderness of the West. Jefferson was an avid naturalist and took great interest in the fossil bones from Big Bone Lick.

Based on discoveries such as these, the field of vertebrate paleontology was starting to take shape during the late eighteenth and early nineteenth centuries. As discussed earlier, one of the most important leaders in this newly emerging field was the French scientist, Georges Cuvier (Figure 3). At the start of the nineteenth century, Cuvier was a professor of animal

anatomy at the Musée National d'Histoire Naturelle (National Museum of Natural History) in Paris.

An opponent of the theory of evolution, Cuvier's most important contribution to science was the establishment of the extinction of ancient species, based on fossil records. Until the nineteenth century, most philosophers and natural historians had rejected the idea that some species had died out and that new species had evolved over time. Most Europeans held to a strict, literal interpretation of the Bible, which dictated that the Earth was created in just 6 days, only a few thousand years ago. But the fossil record that was just beginning to be unearthed by a handful of paleontologists began to challenge this view.

Although Cuvier remained a Creationist, the fossils he was describing were reshaping his views on the nature of that creation. Cuvier believed in the great antiquity of the Earth and held that more or less modern conditions had been in existence for most of Earth's history. However, in order to explain the extinction of species Cuvier had seen in the fossil record, he invoked periodic 'revolutions' in Earth's history. Each 'revolution' was a natural event that had brought about the extinction of a number of species. Unlike others of his time (notably, the Reverend William Buckland, who invoked the Biblical Flood), Cuvier did not equate these 'revolutions' with Biblical or historical events.

Cuvier considered that the last great 'revolution,' the one that had brought about the extinction of such spectacular animals as mammoths and mastodons, might have been a severe and sudden cooling of the planet. Louis Agassiz (Figure 4) took this idea and developed it further, into the concept of a 'Great Ice Age.'

Agassiz was a Swiss naturalist who started his career as Cuvier's assistant. Agassiz thought that mammoths and other extinct mammals must have been adapted to a tropical climate. Here is how he described their demise in the face of the oncoming Ice Age:

The gigantic quadrupeds, the Mastodons, Elephants, Tigers, Lions, Hyenas, Bears, whose remains are found in Europe from its southern promontories to the northernmost limits of Siberia and Scandinavia ... may indeed be said to have possessed the earth in those days. But their reign was over. A sudden intense winter, that was also to last for ages, fell upon our globe; it spread over the very countries where these tropical animals had their homes, and so suddenly did it come upon them that they were embalmed beneath masses of snow and ice, without time even for the decay which follows death (Agassiz, 1866: 208).

The Discovery of Pleistocene Glaciations

Agassiz's theory of the 'Great Ice Age' was first presented to the Swiss Society of Natural Sciences in Neuchâtel in 1837. This was an ideal setting in which to convince geologists and natural historians, because Agassiz could demonstrate the effects of glacial ice in the landscapes of the Alps. He pointed to large boulders that had been transported by ice (glacial erratics), piles of rocks moved by glacial ice (glacial moraines), and scratched surface lines in bedrock, made by the passage of glacial ice and debris. Agassiz published his theory in the books, *Étude sur les glaciers*, in 1840, and *Système glaciaire*, in 1847. These books summarized his findings from Europe. He later found even more evidence of glaciation in North America. Agassiz's theory was initially rejected by many leading geologists, who still held to the idea that the transportation of surficial sediments was due mainly to the effects of the Biblical Flood. Agassiz's ideas on the glaciation eventually won the day, but his ideas about the nature of the Pleistocene megafauna turned out to be largely nonsensical. Far from being tropically adapted animals, the mammoths, mastodons, and other ice-age mammals of Europe were adapted to the very same glacial environments to which Agassiz had ascribed their demise. Most of these animals died out during the transition to warm climate at the end of the last glaciation, not at its beginning.

Evidence for glaciation had been seen by some of Agassiz's contemporaries in other parts of Europe. For instance, Esmark noted the existence of glacial deposits in Norway, Bernhardt found evidence for glaciation in Germany, and de Venetz and Charpentier found evidence for the advance of glacial ice far beyond the limits of modern alpine glaciers in Switzerland. Agassiz himself traveled to Britain and North America and argued that surficial deposits that had previously been considered flood deposits should be reclassified as glacial.

Convinced by Agassiz's ice-age theory, field geologists of the middle and late nineteenth century began looking for evidence to help reconstruct the actual history of glacial events. Agassiz had proposed a single, massive glacial event in which ice sheets covered much of the middle latitudes, as well as the high latitudes of the Earth. Evidence started accumulating that pointed to multiple glaciations, separated by warm periods. By the 1850s, evidence was pointing toward at least two major glaciations in Europe. By 1877, James Geikie (Figure 5) had developed the concept of four or five large glaciations during the Pleistocene on the basis of stratigraphic evidence.

Evidence from North America made it clear that the last glaciation had not been the largest one, because it had not entirely destroyed the evidence for earlier, larger glaciations.

Figure 4 Louis Agassiz (1807–73).

Figure 5 James Geikie (1839–1915).

Geologists coined the terms ‘Nebraskan,’ ‘Kansan,’ ‘Illinoian,’ and ‘Wisconsinan,’ to describe a sequence of four glacial epochs in North America. These were separated by three warm or interglacial periods (the Aftonian, Yarmouthian, and Sangamon) on the basis of the presence of ancient soils buried between glacial deposits.

Pioneering work on establishing the European glacial sequence was carried out by Albrecht Penck and Eduard Brückner (Figure 6), who identified four glaciations, the Günz, Mindel, Riss, and Würm.

These glaciations were named after four rivers in southern Germany. Penck and Brückner’s (1909) work was based on the identification of the stratigraphic sequence of river terraces in the valleys of the northern Alps (Figure 7). In many parts of the world, diligent field studies in the last century have failed to find evidence for more than four glaciations on land.

The ways in which these glaciations were recognized varied from one part of the world to another. In Europe, only the ice advances that reached farther south than the younger ones were recognized as separate glaciations. The traces of any intermediate ice expansion were essentially overridden and destroyed by subsequent larger glacial advances. American glaciations were originally defined as times when the ice sheets extended south to the American Midwest. Interglacials were the times when the Midwest region was free of ice. The classical North American Pleistocene subdivision is one of long interglacials and short glacials, whereas the North European system recognizes short interglacials and long glacials (Kukla, 2005). Penck and Brückner’s Alpine glaciation scheme was the most widely used system of classification in the twentieth century for the correlation of Pleistocene deposits between continents (Flint, 1971).

Figure 6 Eduard Brückner (1862–1927) and Albrecht Penck (1858–1945).

Development of Theories on the Causes of Glaciation

As we have seen, by the late nineteenth century, the geologic evidence for repeated, large-scale glaciations of the globe was firmly established. The causes of glaciation, however, remained a mystery. Geikie’s geologic evidence from Scotland showed that warm intervals had developed between glaciations. While the relative length of glacial and interglacial periods remained unknown, it was becoming clear that large-scale climatic oscillations had taken place over many thousands of years of Earth’s recent history. Various suggestions were put forward to explain these cycles. Changes in carbon dioxide levels were proposed, as well as changes in solar intensity.

Croll’s Orbital Theory

One of the earliest theories on the cause of glacial–interglacial cycles was developed by the Scottish scientist, James Croll (Figure 8). Croll had little formal education, but he was a voracious reader.

In 1859, his pursuit of knowledge led him to enter the academia ‘through the back door,’ by becoming a janitor at the museum at Anderson’s Institution in Glasgow. Once there, he began developing a theory about the causes of glaciation. He began writing letters to Charles Lyell, discussing his ideas on the connections between glaciation and variations in the

Figure 7 Diagram of European Ice Ages, their relative durations, and the relative snow line during each. Note: During glacial periods, snow fell at lower altitudes than during interglacial periods. Gl, glacial; Intergl, interglacial. Reproduced from Penck A and Brückner E (1909) *Die Alpen im Eiszeitalter*. Leipzig: Tachnitz.

Figure 8 James Croll (1821–90). Photo by J.C. Irons (1896).

Earth's orbit. Lyell was suitably impressed with Croll's scholarship and helped him obtain a clerical position at the Geological Survey of Scotland in 1867. It was here that Croll was encouraged by Archibald Geikie to further develop his theory. Charles Darwin also corresponded regularly with Croll, and both scientists benefited from this exchange of ideas.

Croll started publishing his theories in 1867(a,b), and his major contributions include *Climate and Time, in their Geological Relations* (1875) and *Climate and Cosmology* (1885).

In 1846, French astronomer Urbain Le Verrier published formulas that allow the calculation of changes in the shape of a planet's orbit and its axial precession. In 1864, Croll used these formulas to plot changes in the shape of the Earth's orbit (called orbital eccentricity) over the past 3 million years. He found that a pattern of high eccentricity had persisted for hundreds of thousands of years, followed by a pattern of low eccentricity, as is the case today. The more elliptical the orbit, the greater is the difference in incoming solar radiation (insolation) between the different seasons of the year. Croll realized the importance of calculating the seasonality of insolation, which is one of his major contributions to the science of paleoclimatology. Changes in the Earth's orbit that act to prolong the winter season cause greater amounts of snow to accumulate in the high latitudes (Figure 9).

Figure 9 Diagram illustrating Croll's (1887) explanation of Ice Ages, based on changes in the Earth's orbit around the sun.

The extra snow cover reflects more solar energy back out into space, thereby amplifying the orbital effects. Croll argued that this amplification is what triggers the growth of ice sheets.

Croll's theory introduced important new concepts in the field of climatology. Subsequent research has shown that Croll's theory is insufficient to explain the global pattern of Pleistocene glaciations, and his chronology of glaciations has been shown to be in error. Specifically, Croll's scheme made the last Ice Age much older than was inferred from the geologic evidence of Geikie and others. Ultimately, Croll failed to convince most of his contemporaries, and his ideas remained largely ignored by other researchers until the 1940s.

The Milankovitch Theory

Milutin Milankovitch (Figure 10) was a Serbian mathematician who specialized in astronomy and geophysics. In 1909, he became a member of the faculty of applied mathematics at the University of Belgrade.

Imprisoned by the Austro-Hungarian Army in World War I, he recommenced work on his mathematical theory of climate change in 1920, completing this work in 1941. Milankovitch built his theory from previous work done by J.A. Adhemar and James Croll. In 1842, Adhemar explained glacial climate using only precession. Milankovitch used Croll's work to help him develop a mathematical model of climate change. This model incorporates the cyclical variations in the three elements of the Earth's orbit around the sun: eccentricity, obliquity, and precession. Using these three orbital factors, Milankovitch developed

Figure 10 Portrait of Milutin Milankovitch (1879–1958) by Paja Jovanovic (1943). Photo courtesy of Vasko Milankovitch.

Figure 11 Orbital variations predicted by the Milankovitch theory. Reproduced from Berger A and Loutre MF (1991) Insolation values for the climate of the last 10 million years. *Quaternary Science Reviews* 10: 297–317.

a comprehensive mathematical model that calculated latitudinal differences in insolation and the corresponding surface temperatures during the last 600 000 years (Figure 11).

The next step in Milankovitch's work was an attempt to correlate the orbital variations with glacial–interglacial cycles. Milankovitch worked on the assumption that radiation changes in some latitudes and seasons are key to triggering glaciation and deglaciation. Working with German climatologist Vladimir Koppen, he chose the summer insolation values at 65° N as the critical latitude and season. Their reasoning was

that the continental ice sheets grew near this latitude and that cooler summers might reduce summer snowmelt, leading to a buildup of snow pack and eventually to the growth of ice sheets.

Sadly, Milankovitch's theory was largely ignored for decades. However, Hays et al. (1976) published a study of deep-sea sediment cores and found that Milankovitch's predictions matched their own interpretations of the timing and intensity of climate change during the last 450 000 years. Specifically, they found that major variations in climate were closely associated with changes in the eccentricity, obliquity, and precession of the Earth's orbit.

The Invention of Dating Methods

Without a means of obtaining an absolute age for events in the Quaternary, there would have been no way to test the validity of Milankovitch's orbital variation theory. Until the latter half of the twentieth century, Quaternary scientists lacked the tools to obtain such absolute ages and could only infer the ages of events through relative dating techniques. In other words, they could sometimes establish the *sequence* of events, for instance, by determining the relative stratigraphic position of various kinds of fossils. But they could not tell whether a given sequence of events took place 50 000 or 150 000 years ago, unless they were dealing with long sequences of sedimentary layers that had accumulated in recognizable, annual layers (a very rare phenomenon).

Uranium-Series Dating

Radiometric dating methods were developed in the twentieth century and have now revolutionized Quaternary science. In 1902, physicists Ernest Rutherford and Frederick Soddy discovered that radioactive elements broke down into other elements in a definite sequence or series through the process of nuclear fission. The possibility of using this radioactivity as a means of measuring geologic time was first discussed by Rutherford in 1904. In 1906, Rutherford began calculating the rate of radioactive decay of uranium. This decay process (uranium decaying to lead) has since been discovered to go through multiple steps, with intermediate daughter products. It is now possible to use various uranium-series decay processes to derive age estimates for uranium-bearing fossils and sediments that had existed many millions of years ago.

Radiocarbon Dating

Perhaps the most important breakthrough in the absolute dating of Quaternary fossils and sediments was the invention of radiometric dating methods, especially radiocarbon dating. In 1940, American physicists Martin Kamen and Sam Ruben discovered the long-lived radioactive carbon isotope, carbon-14. Kamen used ^{14}C as a tracer in biological systems. Kamen found that some of the nitrogen in the atmosphere was turned into carbon-14 when bombarded with cosmic rays. The existence of ^{14}C had been postulated since 1934, but it had never been directly observed nor characterized. Kamen succeeded in

Figure 12 Photograph of Willard F. Libby, inventor of the radiocarbon dating method. Photo courtesy of Geoscience Analytical Inc.

preparing ^{14}C in sufficient amounts to determine its half-life (5700 years), that is, the amount of time it takes for half of a sample of ^{14}C to break down to the stable ^{14}N isotope of nitrogen.

Building on Kamen's discoveries, in 1947, American chemist Willard Libby ([Figure 12](#)) determined that plants absorb traces of ^{14}C during their uptake of carbon in photosynthesis. At death, the plant would stop absorbing carbon, and the ^{14}C it contained would decay at its usual rate without being replaced. By measuring the concentration of ^{14}C left in the remains of a plant, [Libby \(1952\)](#) discovered that it was possible to calculate the amount of time since the plant had died. In addition, it was found that the same concentrations of ^{14}C occur in the tissues of animals as in plants, since animals either directly or indirectly ingest the carbon from plant tissues as their food. Given that it is possible to measure the concentration of the remaining ^{14}C back to nine or ten half-lives, it has thus become possible to obtain absolute age estimates of fossil specimens (both plant and animal) that existed about 45 000–50 000 years. For his work on carbon-14 dating, Libby received the Nobel Prize in chemistry in 1960.

Luminescence Dating

Thermoluminescence (TL) dating is based on the fact that natural minerals can absorb and store energy from ionizing radiation. If a mineral is heated to a sufficiently high temperature, some of the stored energy is released in the form of light called TL. In nature, the energy absorbed by a mineral mainly comes from radiation emitted from radioisotopes within the mineral grain, from its immediate surroundings, and from cosmic rays. This energy is stored in the form of electrons that get trapped at defects in the crystal lattice of some minerals, notably, quartz and feldspar. These trapped electrons build up slowly through time and are released when the mineral is exposed to sunlight or when it is sufficiently heated. TL dating therefore provides a method of dating the time that has elapsed since mineral grains were last exposed to sufficient heat or sunlight. [Daniels et al. \(1953\)](#) first noted the potential of using TL dating in geological and archaeological research, and it was developed in the early 1960s as a means of dating fired pottery ([Aitken et al., 1964](#)). The technique was later modified

so that it also could be used to date the last time that sediments were exposed to sunlight.

Optically stimulated luminescence (OSL) dating is based on the fact that if a mineral is exposed to sufficient light (e.g., sunlight), some or all of this stored energy will be lost. OSL dating developed from TL dating in the mid-1980s ([Huntley et al., 1985](#)). Its main advantage over TL dating is that only the most light-sensitive signal is sampled, which allows for much younger samples to be dated. Moreover, OSL dating usually results in better precision. These two methods have contributed significantly to Quaternary science in that they allow researchers to obtain dates from mineral grains, rather than just from organic compounds (the basis of radiocarbon dating). Furthermore, OSL dating typically provides useful dates (e.g., quartz grains) ranging from a few centuries to about 150 000 years, well beyond the limits of radiocarbon dating.

Conclusion

Other articles in this encyclopedia will highlight the state of the art in the aforementioned fields of Quaternary stratigraphy, vertebrate paleontology, Pleistocene glaciology, paleoclimatology, and dating methods. As with all branches of science, the current generation of researchers have built on the foundations of people such as Agassiz, Lyell, Cuvier, Milankovitch, and Libby. We owe these pioneers an enormous debt of gratitude. Many of these people worked in relative obscurity during their own lifetimes, and their theories were openly ridiculed by their contemporaries. Many survived major political upheavals and wars in the rapidly changing world of the nineteenth and twentieth centuries. The unifying themes of their lives are their intellectual curiosity, their diligence and perseverance, and their breadth of vision. May the same be said of twenty-first century Quaternary scientists by future generations.

The first methods for dating Quaternary materials resulted from the discovery of radioactivity 120 years ago. In addition, other dating methods have been developed that rely on other time-dependent changes that occur in natural materials. The different methods can be used to obtain the age of formation of either organic or inorganic materials.

Early Developments

Numerical dating methods based on natural radioactive phenomena were initially developed as a means of determining the age of the Earth (Dalrymple, 1991). Arguments on this topic raged in the second half of the 19th century, a time when the effects of recent glaciation were also being debated. However, it was not until the discovery of radioactivity in the 1880s that consideration was given to radioactive isotopes for use as natural clocks. As early as 1906, Rutherford suggested that ages could be obtained based on the production of helium by the decay of uranium in rocks. The first calculation of the age of the Earth based on the amount of radium in the Earth's crust was made by Russell in 1921. However, it was not until the 1930s, when Nier brought together the understanding of natural isotopes in the uranium and thorium decay chains and the construction of the first mass spectrometers, that it became possible to measure a range of isotopes. Also at this time, the potential of several different decay series that could be used for dating was proposed, based on a better understanding of the atomic structure of elements in the periodic table. The relationship between these early radiometric dates and the evolution of the geological timescale has been covered in a history of the work of Arthur Holmes (Lewis, 2000).

Radiocarbon Dating

The speed at which new geochronological tools based on radioactivity became relevant to Quaternary geology can be seen by examining the prefaces to the 1958 edition of Zeuner's book *Dating the Past*. In 1946, when the first edition was published, geochronology was very much based on the study of superposition of geological deposits and botanical and zoological successions. By the time of the third edition in 1952, theoretical and practical approaches to radiocarbon (^{14}C) dating had been put forward by Libby and the first radiocarbon laboratory was established. Soon after, lists of radiocarbon dates started to appear, although at this time radiocarbon dating was mainly applied to archaeological materials, particularly from Upper Paleolithic sites. Another important result of the application of radiocarbon dating was in providing a chronology for the development of farming in Europe and the Near East. Libby was at the heart of radiocarbon dating development for three

decades, producing the first book on the topic in 1952 and receiving the Nobel Prize in chemistry in 1960 for his work on radiocarbon dating. A comprehensive history of radiocarbon dating, and one that demonstrates the role played by Libby, can be found in Chapter 6 of the book by Taylor (1987) and in the edited volume by Taylor et al. (1992).

The early measurement of beta particles released from solid carbon was rapidly replaced by the use of more efficient counting systems using gases or liquids made from the organic material being used for dating. Both methods enable dating back to 60 ka, although the dating range is usually limited to approximately 40 ka due to sample contamination. In the 1950s, gas counting using carbon dioxide, methane, or acetylene was introduced and continued to be used for many decades. These gases (CO_2 , CH_4 , and C_2H_2) contained molecules with ^{14}C in their structure. Preparing the sample as a gas had the additional advantage that it was possible to enrich the concentration of ^{14}C relative to ^{12}C and ^{13}C in part of the gas volume and thus extend the potential age range back to 75 ka (Grootes et al., 1975). This process was known as isotopic enrichment.

In the 1960s, liquid scintillation counting using benzene (C_6H_6) as the carrier of the ^{14}C was developed. Benzene was easy to prepare directly from acetylene. As a liquid, it had two advantages: It was possible to mix the sample and the organic scintillator chemicals, and it had a far greater density than acetylene and thus took up a smaller volume in the counting equipment. The latter property enabled a reduction in background count rate, and by the 1970s, automated liquid scintillation measurement systems were set up in laboratories worldwide.

The next major breakthrough in measurement techniques came in the 1970s, when methods were put forward in which it was not necessary to measure the beta particles released as the ^{14}C atoms decayed. The objective was to measure the ratio of ^{14}C to the more stable isotope of carbon (^{12}C) using a mass spectrometer. The first results were achieved using a particle accelerator known as a cyclotron, which had the advantage of removing all interfering particles except ^{14}N . In other studies, electrostatic accelerators were used in which molecules with similar charge-to-mass ratios as ^{14}C needed to be removed before being allowed into the mass spectrometer. Destruction of these molecules was accomplished by ionizing the sample and accelerating the ions, prior to passing them through a foil. Subsequently, small accelerators were built and the measurement technique of accelerator mass spectrometry (AMS) was born (Hedges, 1981). Being able to measure the atoms directly and not have to wait for them to decay speeded up measurement time. It also led to the dating of very small samples containing only 1 or 2 mg of elemental carbon. This led to a revolution in applications. A significant development has also been made in sample preparation using acid–base–wet

Figure 1 Long-lived bristlecone pines growing in the White Mountains, California, used to provide a tree-ring record for radiocarbon calibration. Photo by Mike Walker.

oxidation and target production for AMS measurements. This has resulted in finite ^{14}C ages older than 50 ka being obtained for charcoal.

The development of radiocarbon dating was not without minor setbacks. Early tests of the dating technique were carried out on material from the tombs of the ancient Egyptian kings. In the 1960s, extensive sets of measurements were carried out on tree rings for which calendar ages could be determined by counting the rings. This method of dating is known as dendrochronology; the first tree-ring laboratory was set up in Arizona in 1937. Radiocarbon ages were obtained on rings from continuous and overlapping sequences cut from dead and living examples of the bristlecone pine, a tree that grows high up in the White Mountains of eastern California (Figure 1). When the radiocarbon ages were compared with the calendar dates from the counted tree-ring chronology, a significant deviation was observed for samples older than 3000 years old. This deviation was the result of long-term changes in the production rate of ^{14}C in the upper atmosphere.

By 1986, calibration curves from many laboratories were brought together and a combined calibration curve was published. Use of bristlecone pines and fossil trees from Ireland and Germany resulted in a continuous calibration curve (IntCal98) for radiocarbon ages (Stuiver and Van der Plicht, 1998) back to 10 299 years BP. A new replacement calibration curve (IntCal04) has been constructed back to 26 000 years BP using paired radiocarbon and uranium series dates on corals and Foraminifera (Reimer et al., 2004).

Potassium–Argon and Argon–Argon Dating

The potential of dating using the decay of ^{40}K to ^{40}Ar was first reported in 1948. The K–Ar technique was developed in the 1950s for determining the age of rocks (Dalrymple and Lanphere, 1969); the first studies were mainly on pre-Quaternary rocks because of the difficulty in measuring the small amounts of argon that have accumulated in the younger rocks. The $^{40}\text{Ar}/^{39}\text{Ar}$ dating method, in which it is not necessary to measure absolute abundances of either argon or potassium in the sample, was developed in 1966. In the first study, it was

Figure 2 A lava flow on Etna that would provide a record of magnetic field direction and that could be dated by the potassium–argon method.

noted that the new procedure would result in more precise ages, would allow measurements on very small samples, and could provide information on the thermal history of crystalline materials if step heating was used. In the early 1970s, such experiments were carried out on a range of terrestrial rocks, with comparisons being made with conventional K–Ar dating.

An important application of both techniques was the dating of lava flows (Figure 2), particularly since they contained evidence of the direction of the Earth's magnetic field at the time that they cooled. During the Quaternary period, the Earth's magnetic field has changed direction several times and the record of these changes is also found in sedimentary rocks (e.g., deep-sea cores and loess). At approximately the beginning of the Quaternary, the field changed from being in the direction that it is today to being totally reversed, and then at approximately 780 ka it changed back again (Jacobs, 1994). These periods of different direction are referred to as chrons and are named after scientists who have studied magnetic behavior. The change from the Gauss normal chron to the Matuyama reversed chron was dated to 2.47 Ma, and the change from the Matuyama chron to the Brunhes normal chron was first dated by the potassium–argon method to 730 ka. Most recently, an age of 775.6 ± 1.9 ka has been obtained using the $^{40}\text{Ar}/^{39}\text{Ar}$ method. Within the Matuyama reversed chron, there were a number of times when the field direction was normal for a few thousand years; these subchrons, named after places where they were first recorded, occurred at approximately 0.9 Ma (Jaramillo), 1.11 Ma (Cobb Mountain), 1.7 Ma (Olduvai), and 2.1 Ma (Reunion). These reversals have been the subject of extensive K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ dating studies during the past 30 years (Jacobs, 1994). This record of reversals has been found in the 195 m of loess that overlies red clay in the Chinese Loess Plateau. This has allowed the transfer of an independent age scale onto the loess and the demonstration of the coincidence of the loess/red clay transition and the beginning of the Quaternary.

This geomagnetic polarity timescale has also been used, often in conjunction with other dating techniques, to obtain ages for sediments containing skeletal remains of early

hominids in Africa. In the Turkana Basin of East Africa, the paleomagnetic history recorded in the sediments has been used along with K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ dating to provide a framework for the archaeological material found therein. In exposed sections, layers of volcanic ash (tephra), known as tuff, can be seen, relating to explosive eruptions of volcanoes hundreds of kilometers to the north. The first K–Ar age was for the KBS Tuff, found above the remains of an important skull of *Homo habilis*. However, the age was severely overestimated as a result of the incorporation of detrital minerals during fluvial reworking of the ash after it had been laid down. During the next 20 years, this tuff and approximately 20 others have been dated (and redated) as technological advances have been made (McDougall, 1990; McDougall and Harrison, 1999). The KBS tuff (named after the graduate student who had found stone tools within the ash layer) and the controversy generated by the dating of it and other tuffs were the subject of two chapters in Lewin's book (1987) on human origins in Africa. In the decade that followed the announcement of the first K–Ar date on the KBS tuff, a number of new measurements were carried out, concentrating on the separation of crystals of anorthoclase (a plagioclase feldspar found in the pumice clasts). These were used for both conventional K–Ar dating and $^{40}\text{Ar}/^{39}\text{Ar}$ dating using step heating, a process that would identify the presence of partially heated grains. By 1981, an age of 1.88 ± 0.03 Ma was accepted for the KBS tuff.

At approximately the same time, it was demonstrated that laser light focused onto a small spot on the surface of a grain could release argon. By the end of the 1980s, it became possible to obtain $^{40}\text{Ar}/^{39}\text{Ar}$ ages on individual grains of potassium-rich feldspars of Quaternary age, with the first results for samples of pumice and other volcanic material from a site in Kenya being published in 1990. This method became known as single crystal laser fusion (SCLF) dating (Walter, 1997). In the next few years, this method was employed on crystals from other hominid sites in Kenya and in Ethiopia. The earlier dates that had been obtained for the Turkana Basin by conventional K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ techniques were confirmed by the new SCLF technique. On a more recent timescale, SCLF methods were used for sanidine crystals from the Laacher See Tephra in the Eifel region of Germany. Combining the ages for 16 individual crystals, an age of 12.7 ± 0.8 ka was obtained for the eruption.

The ability to use $^{40}\text{Ar}/^{39}\text{Ar}$ for Holocene volcanic samples has been demonstrated using subsamples made up of a few tens of sanidine crystals, feldspars with very high potassium contents. These crystals, up to approximately 1 mm in diameter, were extracted from a pumice clast from the city of Pompeii, buried by the eruption of Vesuvius in 79 AD. The age of 1925 ± 94 years before 1997 AD was obtained not by laser fusion but by using incremental heating of the grains, thus taking methods of analysis to an even higher level. A review of the principles and methodology of K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ dating has been published by Renne (2000).

Fission Track Dating

Explosive volcanic eruptions not only produce potassium-rich feldspars but also produce volcanic glass and small zircon and apatite grains. These materials are suitable for yet another

dating method, fission track dating (Westgate et al., 1997). Fission track dating is based on fission of the uranium isotope ^{238}U , a process that has a half-life of 8.2×10^{15} years. The use of fission tracks for dating was born out of the study of fissile material during World War II. Fission is the name given to the process in which an atom spontaneously breaks apart with a tremendous release of energy. In the case of ^{238}U , two nuclei (fission fragments) are formed. They travel through the crystal away from the site of the parent ^{238}U atom in opposite directions, creating a damage trail that is a few micrometers long and approximately one-hundredth of a micrometer in diameter. This damage trail can only be seen as a fission track when the mineral face containing the track is exposed to a chemical etchant that attacks the damage zone along the length of the track. The number of tracks that cross the polished face of the mineral is proportional to the age and ^{238}U content. To obtain an age, this track density is compared with that induced by irradiating the mineral with neutrons, a process that causes the less abundant ^{235}U atoms to undergo fission. The tracks caused in this way are etched and measured as for the spontaneous tracks formed in nature by ^{238}U .

Because the tracks can be removed by heating (annealing), fission track measurements have also been used to determine the time since some thermal event subsequent to the formation of the mineral grains (thermochronology). The historical development of fission track measurement methods was discussed by Fleischer et al. (1975), and a more recent account of fission track dating over the whole of geological time was provided by Wagner and van den Haute (1992). This book also includes discussion of how two different values for the fission half-life were used for many years; this resulted in ages up to 20% different, depending on which half-life was used in the age equation. This problem was resolved by using standard minerals of known age (as obtained by $^{40}\text{Ar}/^{39}\text{Ar}$ dating).

For Quaternary volcanic events, dating has been limited to the use of zircon and apatite grains and volcanic glass. Zircon is the mineral of choice because of its high uranium content; zircon grains will thus have proportionally more tracks than volcanic glass for the same time period. However, very few zircon grains are usually found, perhaps as little as one grain in 1 kg of volcanic sediment (Dumitru, 2000). One of the earliest successes in fission track dating of zircon was the establishment of different ages for a number of volcanic ashes derived from the Quaternary volcanoes in Yellowstone National Park. Two geochemically different examples of the Pearlette Ash, previously used as a time-marker horizon, were found to have ages of 1.9 ± 0.1 and 0.6 ± 0.1 Ma, in agreement with K–Ar ages for two ashes closer to the source.

Even when present, zircon grains tend to be small and thus quite a few are needed to make a reliable measurement. The counting of several grains has the advantage of being able to identify contaminant grains. In the case of a volcanic ash bed in Ethiopia, it was found that the sample contained two populations of zircon grains (Walter, 1989). The ash was dated to 2.3 ± 0.5 Ma by dating the younger grains, but it was shown to contain grains with an age of 13.1 ± 3.2 Ma. If the different track densities had not been noticed, an age of 4.0 ± 0.7 Ma would have resulted.

Because of the scarcity of zircon grains, volcanic glass is usually preferred for Quaternary deposits. Early ages on glass

were found to be too young compared with zircon ages from the same tephra. This was the result of the more rapid annealing of tracks in the case of volcanic glass. To overcome this problem, it was suggested that both irradiated and unirradiated aliquots should be heated to different temperatures for fixed periods of time prior to etching. When a temperature is reached for which the measured track densities are in a fixed ratio, this ratio can be used to obtain the age of the glass.

A more widely used approach has been developed using a lower temperature and longer times. This approach is known as isothermal plateau fission track (ITPFT) dating. More recently, a relationship between the average diameter of the fission tracks and the track density has been found; both are reduced by thermal annealing. ITPFT dating of volcanic glass has proved invaluable for dating ash layers found in the loess deposits of Alaska (Figure 3), the Yukon, and New Zealand (Westgate et al., 1997). A major result of the application of fission track dating of volcanic glass was the dating of the Toba tephra from western India, which, together with geochemical analysis of all known occurrences, firmly establishes that it has a single age, namely 75 ka.

Luminescence Dating

Another method that measures the effect of nuclear processes in minerals is based on the luminescence properties of quartz and feldspars. Unlike fission track dating, it is the effect of ionizing radiation resulting from the decay of ^{238}U , ^{235}U , ^{232}Th , and ^{40}K in the minerals and their surroundings that

Figure 3 Volcanic ash (Old Crow tephra) from Alaska that has been dated by the fission track method. The ash is overlain and underlain by loess that has been dated using luminescence techniques. Photo by Helen Roberts.

results in the age-dependent signal. Unlike most of the other dating methods, luminescence dating techniques do not provide the age of formation of the quartz and feldspar grains to which they are applied. Instead, they determine the point in time at which the grains were either heated or exposed to light. For sedimentary grains, determining the time since the grains were last exposed to light provides the depositional age. This has allowed direct determination of rates of sediment accretion.

Luminescence dating was born out of the need to measure the amounts of ionizing radiation in a laboratory handling radioactivity, or in the environment or as a result of nuclear explosions, and the ability to make the measurements provided by the development in the 1940s of a sensitive light-measuring device known as a photomultiplier tube. The earliest use of thermoluminescence (TL) for dating both archaeological and geological materials was in 1953, but it was not until the 1960s that it was developed as a useful tool. The TL is released from irradiated minerals when they are heated from room temperature to 450 °C in an oxygen-free environment. TL measurements on mineral grains extracted from pottery, which would have had their signal removed by heating during manufacture, were first made in 1964. For the next two decades, TL dating was confined to heated materials, including burnt flint and lava flows. The technical aspects of TL dating are fully covered by Aitken (1985). However, as early as the mid-1960s, TL ages for unheated sediments had been reported in the Russian literature, but they remained unnoticed in the West until the late 1970s when the dating of mineral grains from a deep-sea core was reported. During the next 15 years, TL dating was applied to a wide range of terrestrial deposits ranging from coastal dunes to loess.

The next major breakthrough was in the use of an optically stimulated luminescence (OSL) signal (Huntley et al., 1985). The use of an optically stimulated signal was seen as clearly more appropriate for measuring a signal whose resetting mechanism was exposure to light. Indeed, a light-insensitive TL signal remained when sedimentary grains were exposed to light, either from the Sun or from laboratory light sources. OSL techniques became more widely used when small halogen bulbs, and then light-emitting diodes (LEDs) (Figure 4),

Figure 4 A luminescence dating laboratory showing blue light used for optically stimulated luminescence dating of sand grains. Photo by Risø National Laboratory, Denmark.

replaced the expensive argon ion laser used as the stimulation source.

A peculiar optical stimulation resonance for feldspars, but not quartz, was found in the infrared (IR) region of the spectrum. The availability of IR-emitting diodes soon led to the dating of feldspars using infrared-stimulated luminescence (IRSL). This signal is rapidly zeroed by sunlight, thus making it suitable for dating sediments. The ease of zeroing the IRSL in a relatively short time using such diodes led to the development in 1991 of measurement procedures that could be applied to single portions (aliquots) of K-feldspar grains. This permitted multiple measurements of the equivalent dose (the measure of the past radiation exposure that is proportional to age) to be made.

The stability, power, and wavelength availability of LEDs has led to a rapid growth in methodological developments in the past 10 years (Wintle, 1997; Aitken, 1998). LEDs producing intense blue-green light became available, and a procedure was developed for quartz based on the use of a single aliquot. The single-aliquot regenerative dose procedure is now the basis of most OSL dating applications. IRSL, or OSL, dating of feldspars is less widely applied since for many feldspars the luminescence signals are unstable over geological time (a phenomenon known as anomalous fading). Overcoming this problem for feldspars and getting around the early saturation of the OSL signal for quartz are the current challenges. It should be noted that because of early saturation of the OSL signal found for all quartz, older sediments that are known to be made up of well-bleached grains (e.g., coastal dune ridges) have continued to be dated using a light-sensitive TL signal from quartz.

Also, since the past decade, it has become possible to use a small laser to produce a beam of green light focused onto a 20- μm -diameter spot to obtain OSL from single quartz, or feldspar, grains. This has enabled the measurement of several thousand grains to be carried out and, depending on the brightness of the individual grains, the equivalent dose to be determined for a large number of them (Duller, 2004). Whether these values of equivalent dose form a single population or are scattered enables conclusions to be drawn about whether the grains making up a sediment unit were all well exposed to light at deposition. This is particularly important when sediments of glacial origin are to be dated or when postdepositional reworking is a possibility.

Electron Spin Resonance Dating

Another mineral property that provides a measure of past radiation dose is electron spin resonance (ESR). ESR measurements are made by placing a small aliquot of sample in a magnetic field and observing the amount of microwave energy that is absorbed. This relates to the trapped electrons in the crystalline structure and is proportional to the age since formation (Grün, 1997). The idea of measuring trapped electrons by their behavior in a magnetic field was first put forward in 1936. However, it was not until 1975 that it was used to date a speleothem. In this case, it was used to determine the time that had elapsed since the formation of the calcite that makes up the stalagmite or stalactite. In the 1980s, there was a considerable amount of investigation of ESR as a dating method

for a wide range of Quaternary materials, with the first use for dating corals from raised beaches to establish a terrestrial record of high sea levels. Also in the 1980s, ESR was explored as a method of dating minerals affected by the pressure produced at active faults. It has also been demonstrated that there are particular ESR signals in quartz grains that can be zeroed by sunlight and this would enable sediments to be dated in a way that is analogous to OSL dating. The first measurements of these signals in single grains are also encouraging. Single-grain ESR measurements on quartz grains of volcanic origin have also provided an age for the Toba eruption of 74 ka, albeit with a large amount of scatter.

The potential of using the signal from tooth enamel was investigated in 1987, and by the early 1990s, ESR dating had been applied at a number of sites containing evidence of modern humans. Tooth enamel is made up of hydroxyapatite, a material that provides sufficient ESR sensitivity and remains unaltered during burial. However, the dentine and cementum that make up the rest of the tooth absorb large amounts of uranium from the groundwater that moves through the surrounding sediment, and this has led to the need to model the dose rate through time. Until recently, the upper and lower limits for ESR ages have been calculated using the 'early' or 'linear' uptake models. Such calculations were used in the dating of animal teeth from the Paleolithic site of Pech de l'Azé in France (Grün and Stringer, 1991). Unfortunately, for samples around 150 ka, there is a 40-ka range of values as a result of the uncertainty as to when the uranium was absorbed by the dentine attached to the teeth being dated. In 1993, newly developed thermal ionization mass spectrometers were used for measuring U and Th isotopes when present in low concentrations in very small samples. For teeth beyond the usual range of U-series dating, some assumptions still need to be made about when the uptake of uranium occurred, but the ages obtained with the two extreme hypotheses are much closer, for example, resulting in a concordant age of approximately 400 ka for two teeth from the Hoxne interglacial site. More recent developments in U-series methods using laser ablation to provide atoms for the mass spectrometer have enabled even greater precision, with the isotope contents being obtained spatially across a thin section cut from a tooth (Figure 5).

Uranium Series Methods

The radioactive decay processes of the uranium (^{238}U and ^{235}U) and thorium (^{232}Th) decay chains were investigated in 1938, but at that time the main interest was in the lead isotopes that are at the ends of each decay chain (^{206}Pb , ^{207}Pb , and ^{208}Pb , respectively). In between these lead isotopes and the parent isotopes are a series of daughter isotopes of various elements, each daughter being radioactive. Each of these daughter isotopes will have different chemical properties, with solubility being the most important. ^{230}Th is a daughter product in the ^{238}U decay chain. Thorium (in the form of either ^{230}Th or ^{232}Th) is much less soluble in water than uranium and as a result it is not found in groundwater. Thus, stalagmites and stalactites (Figure 6) formed in caves will take ^{238}U (and its daughter product ^{234}U) into the calcite

structure as they are formed. ^{230}Th is then produced as the uranium isotopes decay. This in-growth of ^{230}Th increases with time and provides a chronological tool for such materials (Schwarcz, 1997).

The earliest applications of ^{230}Th measurements were made in the 1950s and 1960s and applied to lacustrine carbonates, marine sediments and corals, as well as to cave calcite deposits. Until the 1980s, measurements were made by dissolving samples, depositing the isotopes onto metal disks, and then counting the alpha particles released. The isotopic source of each alpha particle could be recognized by its characteristic energy, a technique known as alpha spectrometry. This approach enabled ages to be obtained back to approximately 350 ka, but it was time-consuming, particularly for older samples, which

required several days of counting. Also, relatively large samples were required to obtain high enough isotope concentrations for counting levels to be sufficiently above background, and this led inevitably to the incorporation of inappropriate material (e.g., recrystallized or reworked material).

In the 1980s, these problems were overcome by the introduction of mass-spectrometric techniques. Using a mass spectrometer, the ^{238}U , ^{234}U , and ^{230}Th atoms could be measured directly, without waiting for their decay. This meant that small samples could be used, thus reducing the possibility of contamination, and counting statistics were improved so that very small errors could be obtained (e.g., a 2σ error of ± 1 ka for a sample with an age of 125 ka). The procedure was termed thermal ionization mass spectrometry (TIMS). Because of its high precision, TIMS has been applied to a wide range of materials, including speleothem (Richards and Dorale, 2003), marine and lacustrine carbonates (Edwards et al., 2003), and materials such as calcitic flowstones under cave art and ostrich eggshell as well as flowstones that seal off sediments containing other evidence related to early human activity (Pike and Pettitt, 2003). Multicollector inductively coupled-plasma mass spectrometry (MC-ICP-MS) is being developed as an even more precise tool for the *in situ* dating of growth rings in stalactites, such as those shown in Figure 6 (Eggins et al., 2005).

Dating the Past 100 Years

^{210}Pb is another isotope further down the ^{238}U decay chain. It has been used for dating younger materials because of its very short lifetime. It was introduced as a dating method in 1963 and is used for dating sediments from the past 100 years. Although several approaches have been developed (Noller, 2000), the current rate of supply model is most widely used, a method that requires the integrated activity of ^{210}Pb to be calculated for the deposit. Counting methods are employed following sample digestion, but it has been suggested that ^{210}Pb could be measured directly using MC-ICP-MS, as used for the longer lived isotopes in the ^{238}U decay chain. An artificial isotope, ^{137}Cs , has also been used as a marker horizon in even younger sediments.

Cosmogenic Nuclide Dating

During the 1990s, a suite of new techniques for dating appeared in the Quaternary literature (Cosse and Phillips, 2001). These methods are based on the production of isotopes in rocks at the Earth's surface and are collectively known as cosmogenic nuclide dating. Although it had been proposed by Davis and Schaeffer as far back as 1955 that cosmic rays would interact with atoms in minerals at the Earth's surface, it was not until the mid-1980s that this was explored. At that time, AMS measurement of cosmogenically produced ^{14}C (produced in the atmosphere) became possible. Using similar AMS techniques, it was possible to measure the small amounts of radioactive isotopes (^{10}Be , ^{26}Al , and ^{36}Cl) produced in rocks (Zreda and Phillips, 2000). In addition, the stable cosmogenic isotopes (^3He and ^{21}Ne) could be measured by mass

Figure 7 Glacial landscape in Patagonia showing granitic erratic for which an exposure age has been obtained using cosmogenic nuclides (^{10}Be). Photo by Neil Glasser.

spectrometry (Niedermann, 2002). The importance of these techniques is that they are able to provide direct information on the exposure history of both rocks and sediments. Thus, for the first time it was possible to obtain rates for geomorphic processes in the Quaternary.

Two types of application were developed. First, the exposure age of a rock surface can be measured directly because the number of atoms will be proportional to time, with due account being taken of both the production rate and radioactive decay. Second, when rock surfaces are removed by geomorphic processes, it is possible to use two isotopes with different lifetimes and obtain information on long-term landscape evolution. Some of the first applications were to glacial deposits, for which the fresh rock surfaces are exposed to cosmic rays as the result of erosion by glaciers (Figure 7), and to the new rock surfaces provided by meteorite impacts. However, any process that has the potential to move previously buried rocks to the surface in a relatively short time can be investigated using cosmogenic isotopes. Such studies have been used to quantify rates of bedrock weathering (Gosse and Phillips, 2001; Cockburn and Summerfield, 2004).

Amino Acid Racemization

During the past 40 years, several other dating methods have been developed that use changes that occur as a result of chemical processes in the environment. Of these, the most widely applicable is amino acid racemization (AAR), which was first put forward as a dating technique in 1969. Amino acids are the basic chemical units from which proteins are formed and several different types (e.g., alanine and isoleucine) are found in organic materials (Hare et al., 1997).

In the natural environment, these amino acids exist in two molecular forms, known as isomers. However, in living materials, they occur only in one form (L-type), and after death they convert to the other form (D-type) with the passage of time until equilibrium is reached. This process is racemization (or epimerization for some amino acids). Racemization occurs

Figure 8 Ostracod valve suitable for amino acid racemization analysis: 0.8-mm-long SEM image of a freshwater cypridoidean ostracod found in British Pleistocene interglacial deposits of Marine Isotope Stage 9. Image by John Whittaker.

more rapidly when the environmental temperature is higher (e.g., during interglacials). As with any process occurring in biological materials, there are additional complications relating to structure and these have led to some early problems.

One of the earliest applications of AAR dating was to bones at a native American site in California. However, due to the development of AMS ^{14}C dating, the early (apparently pre-Clovis) ages were found to be incorrect. Since then, no further dating of bones has been attempted. Instead, the main applications of AAR have been to mollusks, both marine and non-marine, with isoleucine being the amino acid of choice (Wehmiller and Miller, 2000). Although a study has criticized use of the AAR technique for producing absolute ages, D/L ratios have been useful for providing correlations and relative stratigraphies over areas where there is little temperature variation. A more secure approach would be to use more than one amino acid, an approach currently being tested. New technological developments include the use of multiple collector ion gas chromatography and reverse phase chromatography and the analysis of free (rather than bound within the protein) amino acids. These have permitted the measurement of very small samples, such as a single Foraminifera or ostracod valve (Figure 8).

Another application of AAR has been to ostrich and other ratite bird eggshells. These have the advantage of having a mineral structure that is far less susceptible to diagenetic alteration during burial. Fossil eggshells are often found in association with an archaeological material and have provided chronological information at sites in southern Africa and Australia.

Summary

Besides the methods outlined in this brief overview, other time-dependent changes can be used to establish age equivalence, although they do not give rise to numerical ages. These and other methods are well described in Chapter 7 of Walker (2005). In addition, there are edited volumes covering many of the techniques (Taylor and Aitken, 1997; Noller et al., 2000), as well as review papers dealing with one or more of the techniques discussed here (Wintle, 1996).

Introduction

The great nineteenth century geologist and natural historian, Charles Lyell (1830), is generally credited as being the author of the concept of Uniformitarianism (see [History of Quaternary Science](#)). Simply stated, this concept says that 'the present is the key to the past.' In other words, we may interpret the ancient history of the planet through our understanding of modern-day processes. This concept represented a major step forward in scientific thought, greatly influencing contemporary scientists, such as Charles Darwin (see [History of Quaternary Science](#)). However, in this article the author hopes to make it clear that the reverse of Lyell's concept is equally true: the past is the key to the present. In other words, knowledge of the past is key to our understanding of the present world, especially in the multiple disciplines known as the environmental sciences. No matter which aspect of the environment one considers, be it the atmosphere, the oceans, the cryosphere, the lithosphere, or the biosphere, it is impossible to fully comprehend modern processes and conditions without some knowledge of the past. To try to understand present-day environments without the knowledge of their Quaternary history would be like trying to understand the plot of a very long novel by reading only the last page.

Climate History

The Quaternary period saw a large number of climatic oscillations (see [Introduction](#)) on a scale that was probably greater than at any other time in the last 60 million years (Bradley, 1999). Thus, a study of Quaternary climate change provides us with an understanding of climatic variation on a much larger scale than has been recorded in historical records of the last few centuries. An understanding of the magnitudes and rates of climate change during the Quaternary period is necessary to develop our comprehension of modern climate. Much of climate modeling is based on data derived from reconstructions of ancient climates. These models require long-term data, which are available only in ancient climate records, reconstructed from various kinds of proxies, such as geochemical records from polar ice cores, and terrestrial and oceanic fossil records.

The predicted amplitude of global warming in the twenty-first century varies greatly from one scientific study to another, but in the absence of any mitigating policies, Wigley and Raper (2001) predicted with a 90% probability that by the end of the twenty-first century, global mean temperatures would have risen by 1.7–4.9° C. The [Intergovernmental Panel on Climate Change \(2007\)](#) estimated that in the next two decades, global mean temperatures will rise by 0.2° C per decade. Subsequent

levels of warming will depend on the levels of greenhouse gas emissions. The warming to occur in the coming decades is certainly going to be unprecedented within recorded history, but it falls within the boundaries of more than one previous interglacial period, including the last interglacial (ca. 120 000–115 000 years ago), when mean temperatures were substantially warmer than they are today in many parts of the world. Evidence from the Vostok Ice Core in Antarctica (see [Antarctic Stable Isotopes](#)) indicates that at the beginning of the interglacial, between about 130 000 and 127 000 years ago, regional temperatures climbed as much as 3° C higher than today (Figure 1; Kukla et al., 2002). As Velichko et al. (1993) observed, there is abundant proxy evidence of large-scale climatic change during the Quaternary, especially in the northern high latitudes. During the long series of glacial–interglacial cycles, high latitude temperatures appear to have fluctuated within about the same range that is projected for the next century (see [Paleoclimate Relevance to Global Warming](#)).

Predictions of future temperature changes, based on orbital forcing and increased greenhouse gas concentrations in the atmosphere (Loutre and Berger, 2003), suggest that anthropogenic (human-induced) effects may force global climate into an interglacial mode that may persist for 30 000–40 000 years, not unlike an interglacial period that occurred about 405 000–340 000 years ago.

Pace of Climate Change

Global warming is predicted to increase at a much faster rate in the coming decades than the rates of temperature change observed in recent centuries. For instance, Vinnikov and Grody (2003) analyzed upper atmospheric (troposphere) temperatures for the interval 1978–2002, and from these data they inferred a future global warming trend of 0.22–0.26° C per decade. Has the Earth previously experienced temperature changes as rapid as this? Fossil beetle evidence from Britain indicates that even greater rates of warming have occurred in the past. For instance, at the end of the last glaciation, the temperature change during the transition from the glacial climates of the Younger Dryas interval to the postglacial climates at the beginning of the current interglacial was extremely rapid and intense. The beetle evidence (see [Late Pleistocene of Europe](#)) suggests that mean summer temperatures warmed on the order of 0.35° C per decade during this transition (Figure 2; Lowe et al., 1995). This climate change led to wholesale changes in the flora and fauna of many regions. We cannot hope to predict the kinds of changes that may take place in the modern biota without some knowledge of how past biotic communities responded to large-scale climate change.

Figure 2 Reconstructed mean July temperature change during the interval 15,000–11,000 years ago in Britain, based on insect fossil analysis. Data from Lowe et al., 1995.

Ocean History

By studying the Quaternary fossil record from deep-sea sediments, paleoceanographers have come to understand the role of oceans in the transfer of heat from the tropics to the high latitudes, via ocean currents (see [Paleoceanography An Overview](#)). Broecker's (1987) model of the oceanic thermohaline conveyor belt demonstrated the manner of functioning of this system, both in the past and in the present. This thermohaline conveyor belt acts as a major conduit for the exchange of thermal energy, nutrients, and dissolved oxygen between the shallow and deep oceans of the world. There is little doubt that the conveyor belt's capability to transfer heat in large volumes and across vast distances profoundly influences global climate. There is some evidence that the current climatic warming, especially in the high latitudes, may be weakening the thermohaline circulation (Häkkinen and Rhines, 2004). Recent oceanographic research (Curry and Mauritzen, 2005) suggests that the northern regions of the North Atlantic Ocean have been diluted by increasing amounts of freshwater since the 1960s. Climate models indicate that, if the conveyor belt were to shut down, much of Europe would

be 5–10° C colder, the equatorial regions would be 4–5° C warmer, and Greenland would be as much as 16° C colder than it is today. Rainfall patterns would radically change, and the atmosphere would become dustier (Broecker, 1999). Again, without the paleontological data from Quaternary marine sediments, we would have little or no understanding of these phenomena (Figure 3).

Sea Level Change

There is a growing body of evidence that the current level of global warming is going to bring about substantial rises in sea level, as polar ice caps melt. The Intergovernmental Panel on Climate Change (IPCC) (2007) has estimated that sea level will rise 50 cm above current levels by the year 2100 (Figure 4). This is a substantially greater rise in sea level than occurred in the last century. The ecological and human impacts of rising oceans would be substantial, including increased flooding, coastal erosion, salination of aquifers, and loss of coastal agricultural land and living space (IPCC, 2001). The loss of living space is particularly critical, given that 50% of the world's population lives within 6 km of the sea, and that 14 of the 15 largest cities are coastal.

Again, one must refer to the Quaternary record to find sea levels that were as high, or even higher than, the levels predicted for the coming century. Reconstructions of global mean sea level during the last interglacial period (see [Eustatic Sea-Level Changes – Glacial–Interglacial Cycles](#)) place it 6–7 m above modern mean sea level at about 125,000 years ago (Bard et al., 1993; Chappell and Shackleton, 1986). By studying the effects that these higher sea levels had on ancient coastal landscapes, we are able to develop much more useful models of what may happen in the future.

Coastal Deposition and Erosion

As sea levels rise and storm intensity increases with global warming, many of the world's coastlines are being eroded (Figure 5). Needless to say, the impacts on society are relatively large and costly. For instance, a report by the Heinz Center for Science, Economics, and the Environment states that in the United States, approximately 1500 homes will be lost to coastal erosion each year for the next several decades at an

The Atlantic thermohaline circulation
a key element of the global oceanic circulation

Figure 5 Coastal erosion photograph from Peter French.

annual cost to coastal landowners of approximately \$530 million (Heinz Center, 2000). The predictions for coastal change under the scenario of global sea level rise warn of impending disaster for the variety of coastal features and their associated habitats (Psuty and Silveira, 2010).

Of course coastal erosion has been going on for many thousands of years, and has been documented by marine geologists studying Quaternary near-shore deposits. What is happening today is just the most recent episode in an ongoing Holocene marine transgression. The erection of coastal defenses has altered the process, at least temporarily, but ultimately the phenomenon is inexorable. Quaternary geologists have been studying such processes as the supply and sink of coastal sediments, interactions of the retreating shore face with older deposits, and long-term changes in the direction of shoreline changes (see *Sedimentary Indicators of Relative Sea-Level Changes – High Energy*) (McNinch, 2004). They have found that variations in the rates and directions of shoreline change are strongly controlled by changes in ocean wave and tidal energy (van der Molen and van Dijk, 2000). These are highly complex problems that are very difficult to model, but data from Quaternary studies are essential to the process.

Environmental Change in Oceanic Ecosystems

The world's continental shelves are highly productive marine ecosystems (Lohrenz et al., 2002). However, we do not fully understand the role of continental shelves in the global climate system. The science of paleoceanography is providing the kind of information needed to gain a better understanding of

this role. Specifically, we need to know more about changes in continental shelf productivity during times of different sea levels, the storage of nutrients on continental shelves, and the effects of changes in sea level on the total sea surface area. As with the other problems discussed here, these are not just ‘academic’ issues. For instance, they affect the biological productivity and diversity of the oceans, both of which have direct implications for the world’s fisheries.

Cryosphere History

The waxing and waning of ice sheets has been the dominant environmental phenomenon of the Quaternary, either directly or indirectly affecting every region of the globe. In the current climatic conditions, polar ice caps are thinning, mountain glaciers are retreating in most regions, and many are in danger of disappearing altogether. Notable among these are the glaciers and snowfields that are perched on the tops of high mountains near the Equator (see [Africa](#)). A recent study of Mount Kilimanjaro’s summit in Africa (Thompson et al., 2009) showed that 85% of the ice cover that was present in 1912 has disappeared, and that 26% of the ice cover that was present in 2000 has now disappeared. At the current rate of melting, this ice cap will be gone within a few years (Figure 6). This study, based on ice cores from Kilimanjaro, revealed that the processes driving the current shrinking and thinning of the Kilimanjaro ice fields are unique and unrecorded within the last 11 700 years. Similarly, the massive Quelccaya ice cap in the Peruvian Andes is melting (see [South America](#)). The ice cap shrank from 56 km² in 1976 to just 44 km² in 2001, and it may disappear within the next 20 years.

Figure 6 Aerial photograph of the top of Mount Kilimanjaro, showing the remnants of the ice cap. Photograph courtesy of Byrd Polar Center, Ohio State University.

The Antarctic and Greenland ice sheets together hold 33 million cubic km of ice, representing enough water to raise global sea level by 70 m (Rignot and Thomas, 2002). Current research by several different research groups indicates that the Greenland Ice Sheet is thinning, especially near the coasts (see [Dynamics of the Greenland Ice Sheet](#)). The Antarctic story is more complicated. It appears that the West Antarctic Ice Sheet is thinning (Figure 7; see [Dynamics of the West Antarctic Ice Sheet](#)) overall, but it is thickening in some regions and thinning in others (Rignot and Thomas, 2002). Recent modeling of the West Antarctic Ice Sheet by Bamber et al. (2009) indicates that its collapse would raise global sea level by an average of 3.3 meters. Large sectors of ice in south-east Greenland, West Antarctica, and the Antarctic Peninsula are changing quite rapidly, but glaciologists do not yet understand all the processes involved. Modeling is a key element in developing that understanding, and the best sources of data for such models come from paleoenvironmental research. It is clear that just as global climate affects polar ice sheets, so also ice sheets affect global climate. As Clark et al. (1999) have said, given the importance of ice sheets in the climate system, establishing the factors that control their evolution and behavior is necessary for understanding their influence on climate over the long term. This applies equally to questions about the future stability of the polar ice sheets.

Lithosphere History

The study of geomorphology, or the processes that act to shape the surface of the Earth, is rooted firmly in Quaternary science. Understanding Earth’s geomorphic history is the key to understanding current geomorphological problems. Knowledge of contemporary earth surface processes is critical to the study of the hazards and sustainability of the landscape.

Soil Studies

Modern soils in the rich agricultural regions of the middle latitudes of the Northern Hemisphere owe much of their formation to Pleistocene glaciations. Glaciers and ice sheets

Figure 7 Photograph of Pine Island Glacier taken by Tom Kellogg onboard the US Coast Guard icebreaker ‘Glacier,’ 1985, in Pine Island Bay.

pulverized layers of bedrock and organic matter that fell within the ice boundaries, creating the mixtures of sand and silt, and clay that became the best soils in which to grow crops. This is due to their moisture retention characteristics and nutrient storage ability. These soils can be considered part of the world's Pleistocene heritage (see [Overview](#)).

These rich agricultural soils are the product of thousands of years of glacial and postglacial environments. They are quite durable, yet susceptible to degradation through overuse and poor land management practices. Soils in other regions of the world vary in their ability to sustain agriculture. By one estimate ([Oldeman et al., 1991](#)), about 15% of Earth's land surface has been seriously degraded by human activities ([Table 1](#)). Perhaps 25% more of Earth's soils are at risk of serious degradation ([World Resources Institute, 1990](#)). The loss of agricultural land through erosion is estimated at 6 or 7 million hectares (ha) per year, with an additional annual loss of 1.5 million ha as a result of waterlogging, salinization, and alkalization ([Brundtland et al., 1987](#)). Degradation of dry-land soils is now thought to be decreasing plant productivity by 20–40% across the arid and semiarid regions of the globe ([Zika and Erb, 2009](#)). The ever-expanding human population of the world is essentially using up the vital resource of arable soil at an alarming rate. It took many thousands of years for these soils to develop, but only a few centuries for them to degrade.

Geologic Hazards

Our understanding of most geologic hazards has been greatly enhanced by Quaternary studies. The reason we must probe into the past to understand these phenomena is that most of them are highly sporadic and largely unpredictable, despite the best efforts of geoscientists. Catastrophes such as large volcanic eruptions, earth quakes, and tsunamis, take place only rarely in any given region. These phenomena are discussed in a document published by the [United Nations Environment Program \(2005\)](#). The interval between events may be hundreds or even thousands of years – well beyond the span of recorded history. The Quaternary record affords us insights into the timing and intensity of past catastrophic events.

Table 1 1991 soil degradation statistics by region

Region	Human-induced soil degradation (million ha)	Total land surface (million ha)	Percent of land with soil degradation
Africa	494	2966	17
Asia	748	4256	18
South America	243	1768	14
Central America	63	306	21
North America	95	1885	5
Europe	219	950	23
Australasia	103	882	12
World	1964	13013	15

Volcanic Eruptions

Sitting astride the boundaries of the world's tectonic plates, volcanoes are a major hazard to human life in many parts of the world. Volcanic eruptions have claimed more than a quarter of a million lives since the destruction of Pompeii in AD 79 ([Table 2](#)). The principal hazard is not lava, which usually flows sufficiently slowly to allow all but the closest inhabitants to the volcano to escape. Volcanic ash, or tephra, is the principal hazard. It is ejected in far larger quantities than lava in most eruptions ([Figure 8](#)), and it can travel thousands of kilometers, often circling the globe in a plume that is visible from space ([Figure 9](#)). In rare cases, ignimbrites are ejected during volcanic eruptions. These are pyroclastic rocks consisting of glass shards, crystals, and lithic fragments. Ignimbrites are formed by the deposition of hot, rapidly expanding, turbulent magmatic gases. This happened in the 1902 eruption of Mt. Pelee on the Caribbean island of Martinique, killing all but two

Table 2 Major historical volcanic eruptions

Locality	Date	Estimated human death toll
Pompeii and Herculaneum, Italy (Vesuvius)	AD 79	Thousands (uncounted)
Iceland (Laki volcano)	AD 1783	9350
Kyushu, Japan	AD 1793	14 300 (triggered avalanche and tsunami)
Sumbawa, Indonesia (Tambora volcano)	AD 1815	92 000 (10 000 directly; 82 000 through starvation and disease)
Central Ecuador (Mt. Cotopaxi)	AD 1877	1000
Krakatau, Indonesia	AD 1883	36 000
St. Vincent, West Indies (Soufrière volcano)	AD 1902	1680
Martinique, West Indies (Mt. Pelée)	AD 1902	40 000
Northern Columbia (Nevada del Ruiz)	AD 1985	25 000
Total loss of life		>250 000

people on the island. When volcanic ash and rock mix with water, they may form a lahar, which comes sweeping rapidly down the mountain into surrounding valleys. Volcanic tephra layers deposited in Quaternary sediments are the chief means by which scientists reconstruct the history of prehistoric eruptions (see [Tephrochronology](#)). We can say with absolute certainty that some of the volcanic eruptions that took place in the Pleistocene were far greater, and affected larger areas, than anything in recorded history. For instance, 600 000 years ago, the central part of what is now Yellowstone National Park, Wyoming, exploded in an enormous volcanic eruption. The eruption spewed out nearly 1000 km³ of debris. What is now the park's central portion then collapsed, forming a 45- by 75-km caldera (or basin). Tephra from this eruption is known to have blanketed more than 5 million square kilometers of western and central North America ([Smith and Siegel, 2000](#)). If an eruption on this scale were to happen today, it would ecologically devastate large regions, and cause climatic cooling for several years afterwards because of the screening of sunlight by volcanic ash and gases in the atmosphere. To put this Yellowstone eruption into context, the largest volcanic eruption in historic times was in Tambora, in Indonesia, in 1815. This eruption is estimated to have ejected about 150 km³ of ash into the atmosphere ([Oppenheimer, 2003](#)). This is less than one-third the amount estimated for the Yellowstone eruption. Anomalously cold weather hit the northeastern USA, the maritime provinces of Canada, and Europe the following year. 1816 came to be known as the 'Year without a summer' in these regions.

The Yellowstone volcanic eruption story is a cautionary tale. Far greater eruptions have taken place in prehistory than have happened in historic times. Our knowledge of the prehistoric eruptions has come through the analysis of ancient volcanic deposits. Tephrochronology, the study of volcanic ash deposits, has helped scientists determine the source of ash deposits (through chemical fingerprinting). By piecing together regional histories of volcanic activity, Quaternary

scientists have been able to reconstruct the size and timing of ancient volcanic eruptions. By working with modern volcanologists, we have begun the difficult task of predicting volcanic eruptions. The science of volcanic eruption prediction is far from exact, but it has enabled the evacuation of some threatened regions *before* major eruptions took place. For instance, in 1991 volcanologists were able to warn the people living near Mount Pinatubo in the Philippines a few days before devastating eruptions took place. In total, 58 000 people were evacuated from a 30-km radius around the volcano ([Wolfe and Hoblitt, 1996](#)).

Earth Quakes and Tsunamis

There is no doubt that earthquakes and the resulting tsunamis ([Figure 10](#)) have killed more people in historic times than any other geologic hazard. As shown in [Table 3](#), major earthquakes in the past 1200 years are known to have killed more than 4 million people. This total includes more than 2 million people in just the twentieth century. As human populations increase, and the number of poorly built multi-story buildings goes up, these numbers are only likely to grow larger. But, like volcanic eruptions, earthquakes are relatively rare events in any one region, and we have yet to develop a meaningful way of predicting them. Geoscientists may be able to predict that there will be a major earthquake somewhere along a given fault system, but as of now they can only say that it will likely happen within the next decade or the next century. In fact, some of the most useful data in the study of earthquakes comes from Quaternary science. Ancient earthquakes have left behind clear indicators in buried sediments. For instance, [Fumai et al. \(1993\)](#) were able to reconstruct a 100-year recurrence interval for the San Andreas Fault zone, 70 km northeast of Los Angeles, based on sedimentary evidence. Earthquakes caused debris-flow deposits, ruptured, tilted, and folded bedding planes in the sediments.

The timing of an earthquake in the year AD 1700 along the coast of Washington state, USA, was able to be accurately dated through analysis of tree-rings (see [Dendrochronology](#)). [Yamaguchi et al. \(1997\)](#) studied Japanese historical evidence for a large tsunami of previously unknown origin and were

able to pin down the source of the earthquake that caused it. They proposed that a magnitude 9 earthquake in the Cascadia subduction zone of the Pacific Northwest region of North America was the trigger for the tsunami that occurred on 26 January 1700. Tree-ring records from the central Cascadia region (**Figure 11**) support this theory. When the earthquake struck, much of the coast between southern British Columbia and northern California was abruptly lowered, submerging some coastal forests in more than a meter of tidewater. Yamaguchi et al. studied the annual growth rings of some Sitka spruce trees that survived this tidal submergence, and the rings in some trees show changes in width and anatomy consistent with disturbance (tilting, increased flooding, or both) in AD 1700 and a few years afterward.

Tsunamis may also occur in tectonically rather stable areas, as shown by the Storegga Slide that struck the coasts of Scotland and Norway, about 7000 years BP. (Dawson et al., 1988).

Biosphere History

Our knowledge of how ecosystems function has been greatly aided by Quaternary paleontological studies. In the absence of

Figure 11 Tree-ring dating of the 1700 Cascadia earthquake. The dead tree on the right was drowned in salt water due to subsidence during the earthquake. The outermost tree-rings from a number of dead snags in regional salt marshes correspond to the year AD 1700 in tree-ring sequences from living (upland) trees in the region.

such studies, modern ecologists would have little or no idea about the longevity of ecosystems and their resistance to change in the face of large-scale environmental variations.

Longevity, Resistance, and Resilience of Ecosystems

Studies of plant and animal remains from the Quaternary have shown that the current ecosystems are not composed of species that are inherently the best suited for their environments. Rather, modern ecosystems represent just the latest reshuffling of species, and the mixture of species in biological communities at any given time has been shaped by many forces. In the middle- and high latitudes, the catalyst for changes in ecosystems has been large-scale climatic fluctuations of the Pleistocene, accompanied by the waxing and waning of continental ice sheets and mountain glaciers (see [Evidence of Glacier and Ice Sheet Extent](#)). There have been hundreds of these large-scale fluctuations in climate during the last 2.4 million years. Amazingly, some groups of organisms (notably beetles) have remained intact throughout this interval, shifting their ranges in response to climatic change (see [Overview](#)). Other groups, such as mammals, have undergone waves of speciation during the Quaternary (see [Vertebrate Overview](#)). This includes, of course, the hominid lineage that gave rise to our species (see [Overview](#)). Towards the end of the last glaciation, a large number of megafaunal mammals (species with adult weight greater than 40 kg) became extinct. During the middle of the last glaciation, more than 150 genera of megafauna were alive on the planet. By 10 000 years ago, this number was reduced to just over 50 genera (see [Late Pleistocene Megafaunal Extinctions](#)). Thus, approximately two-thirds of the large mammal groups became extinct during this interval ([Figure 12](#)). This extinction event has been the subject of hot scientific debate for the last 40 years.

Pleistocene Megafaunal Extinctions

The conclusion of the debate over the megafaunal mammal extinctions at the end of the Pleistocene rests on determining

Figure 12 Megafaunal mammals that became extinct towards the end of the last glaciation. (a) *Macrauchenia* (South American browser – no living relatives); (b) *Megaloceros* (Giant deer); (c) *Eremotherium* (Ground sloth); (d) *Mammuthus* (Woolly mammoth); (e) *Megatherium* (Giant ground sloth); (f) *Procoptodon* (Giant short-faced kangaroo); (g) *Coelodonta* (Woolly rhinoceros); (h) *Smilodon* (saber-tooth cat).

its cause. Paleontological evidence has shown that previous glacial-to-interglacial transitions in the Pleistocene did not bring about wholesale extinctions of species. This evidence has led some scientists to conclude that human predation was what dealt the final blow to the Pleistocene megafauna, at the end of the last Ice Age (Martin and Klein, 1989; Flannery, 1994). Others believe that changing environments brought about this extinction, and express the view that humans had little or nothing to do with it (Grayson and Meltzer, 2003). A third group of scientists holds a middle view that perhaps people played a part in megafaunal extinction, but that the degree of human impact has yet to be determined (Barnowsky et al., 2004).

Modern Extinction Rates

We may never find the ‘smoking gun’ for the end-of-Pleistocene extinction event, but the fossil record demonstrates that such large-scale extinction events have been rare in Earth’s history. There have been at least five well-documented mass extinctions in the planet’s history. Some, such as the dinosaur extinction, 65 million years ago, are thought to have been caused by meteor impacts. The causes of other extinction events remain unknown. However, the causes of the modern extinction of species are all too obvious. As human populations swell and human land use alters once-pristine ecosystems, the biodiversity of the planet is more and more degraded. For the past 300 years, recorded extinctions of some groups of organisms have shown rates of extinction at least several hundred times the rate expected on the basis of the geological record (Dirzo and Raven, 2003). Even if this rate of extinction has been exaggerated, as suggested by some authors (Stork, 2010), it cannot be denied that the loss and fragmentation of natural habitats is severely affecting the viability of untold numbers of species around the globe.

Human ‘Coming of Age’ in the Quaternary

As we have seen, the study of Quaternary environments and organisms forms the basis for gauging much of what is happening in the modern world. Quaternary science provides the necessary information for assessing the potential impacts of future global warming, recurrence rates for geologic hazards, modern species extinction rates, and a host of other topics of vital interest to humanity. Our own species, *Homo sapiens*, first appeared only about 160 000 years ago (Clark et al., 2003). Although modern societies are quite capable of shaping their immediate environment to suit their needs, for more than 90% of human history, the environment has been shaping us. Our species, and its immediate ancestors, were all products of the Pleistocene, first shaped by environmental changes in Africa, followed by Eurasia, finally colonizing most of the globe within the last 12 000 years (since the end of the last glaciation; see Overview). *Homo sapiens* means ‘wise man.’ Will our species live up to its scientific name?

Introduction

Quaternary science is an interdisciplinary subject concerned with the history of environmental changes on Earth during the past 2.6 My. It is the goal of Quaternary scientists to interpret the geological record from this period in order to understand the key processes (physical, chemical, biological, atmospheric, human-induced) that trigger and modulate environmental change at all geographic and temporal scales. Given this very wide scope, it is not surprising that the technical and intellectual tools required to achieve this goal have been drawn from almost every scientific discipline. The accurate dating of many Quaternary events, for example, became possible only after major developments took place in atomic physics during the first half of the twentieth century; recent discoveries in evolutionary biology and biomolecular analysis have revolutionized our interpretation of the Quaternary fossil record; engineering breakthroughs just after the Second World War enabled sediment cores to be recovered from the deepest parts of the oceans and polar ice caps, the analysis of which revealed for the first time the highly sensitive nature of the Earth's climate; and space exploration has enabled processes at the Earth's surface to be measured and monitored independently.

Applications of these various approaches to the interpretation of Quaternary geological records over the course of the past 80 years or so has significantly changed the way in which we now interpret recent Earth history (Porter, 1999). The analytical tools available for studying the records grow ever more sophisticated and diverse, and past events can now be reconstructed at a much higher temporal resolution than was possible only a few decades ago. What emerges from these analyses is a highly resolved record of global climate change during glacial and interglacial episodes, with shifts in temperature of 10 °C or more, sometimes occurring on millennial or, in some cases, centennial timescales.

Over the past 2.6 My, the Earth acquired the combination of physical characteristics (e.g., shape and disposition of continents and mountain belts, ocean circulation systems, atmospheric gas content, and major vegetation biomes) that we can observe today, and which differ markedly from those of earlier eras. The Quaternary geological record of this time interval has revealed just how frequently, and occasionally spasmodically, the global climate system can change. It provides the basis for testing outputs of Global Circulation Models (GCMs), numerical models that simulate the workings of the present global climate system. It was also during the last 2.6 My that anatomically modern humans evolved, diffused globally, and became increasingly influential in modifying the Earth's surface and atmosphere.

Quaternary scientists integrate information obtained from the natural science disciplines, such as climatology, ecology,

geology, and oceanography, as well as from subjects usually associated with the humanities, such as archaeology and anthropology. This reflects the belief, long held by Quaternary scientists that a multidisciplinary approach is essential for understanding global environmental changes, how their effects might be controlled or mitigated, and how humans might learn to cope with environmental stress – knowledge which could well have a bearing on long-term human survival. This brief review considers the primary methodological developments that underpin current thinking about ways in which climatic fluctuations regulate Earth surface processes and conditions. We begin with the publication of the Astronomical theory, which represented the first systematic attempt to explain the rhythmic nature of Quaternary climate change. Coincidentally, the formulation of the Astronomical theory broadly coincided with the establishment of INQUA, the International Union for Quaternary Research (Porter, 1999). INQUA held its first international congress in 1928 and since then its diverse, multidisciplinary membership has been consistently at the cutting edge of research into global climate change.

Astronomical Rhythm of Climate Change

It had long been suspected that the Earth has experienced periodic changes in climate. The first tentative suggestions about these matters were made in the later years of the nineteenth and early years of the twentieth centuries, although in those times the geological evidence available for testing the emerging ideas was limited and equivocal. Since then, geological archives have become more robust and diverse. Rhythmical change is clearly reflected, for example, in the oscillatory nature of the stable oxygen isotope signal in deep-marine sediments and polar ice cores, in the regular occurrence of well-developed soil units (paleosols) within the thick accumulations of wind-blown dust (loess) in central China, and in an increasing number of lake-sediment records, which suggest that the margins of forests in Europe and in high mountain regions, such as the Andes, regularly migrated backwards and forwards across considerable tracts of land. These are manifestations of a global response to some rhythmical forcing agent, now widely believed to be variations in the Earth's orbit and axis. This is the 'Astronomical' or 'Milankovitch theory', named after the Serbian geophysicist, Milutin Milankovitch who, in a series of papers between 1920 and 1941 (e.g., Milankovitch, 1930), proposed that cyclical variations in the amount of solar radiation received at the surface of the Earth could induce major changes in global climates. The principal components of the theory are the precession of the equinoxes (apparent movement of the seasons around the sun) with a periodicity of ~19–23 ka, the obliquity of the ecliptic (variations in the tilt of

the Earth's axis) with a periodicity of ~ 41 ka, and the eccentricity of the orbit (changes in the shape of the Earth's orbit) with a periodicity of ~ 100 ka.

Developing a convincing means of testing this theory has been one of the notable achievements of Earth science in the twentieth century. This was achieved initially through the detailed analysis of stable oxygen isotope variations in marine microorganisms (Foraminifera) obtained from deep-ocean sediments (Figure 1). The ratio of the lighter oxygen isotope (^{16}O) to the heavier isotope (^{18}O) is mainly controlled by the volume of global ice cover and hence, is an index of global climatic change. Deviations towards heavier ratios (downward swings in the isotope curve) reflect times of increased land-ice cover ('glaciations'), and upward shifts represent warmer periods ('interglaciations') when it was significantly reduced.

This evidence offers a deep insight into how the Earth responds to the external stimulus of insolation (solar radiation), how the incoming radiation signal may influence processes operating at the surface of the Earth, and how the behavior of the Earth's climate at the 105-year scale may be predictable over the long term. Some of the more important features of the Earth's recent climate include the following:

1. As Figure 1 implies, cyclic change in global climate is the hallmark of the Quaternary. There is no evidence in the records of extended periods of climatic stability; instead, the Earth's climate system appears to have been constantly in transition throughout the past 2.6 My.
2. The frequency of the climate cycle changed during the Quaternary. Milankovitch's 'precession cycle' appears to have been predominant during the late Pliocene, between ~ 2.8 and 2.6 Ma; the 'obliquity signal' dominated in the period 2.6–0.8 ka, and the 'eccentricity signal' is characteristic of the last 800 ka (Raymo and Ruddiman, 1992).
3. Whereas the calculated values for variations in insolation vary symmetrically over time (Berger et al., 1999),

measured oscillations in oceanic stable isotope ratios are nonsymmetrical (Figure 1). Rates of warming at the start of interglacial stages are usually more rapid than the more gradual cooling trends leading to glacial stages. The implication is that climate response to astronomical variations is not linear, and that the radiation signal is modulated in some way by processes operating at the Earth's surface.

4. Figure 1 also shows how the amplitude of climate oscillation increased during the Quaternary, particularly within the last 800 ka or so, when the eccentricity cycle was predominant. Interglaciations became generally warmer during the later part of the Quaternary, while glaciations appear to have been characterized by colder extremes than during earlier times.
5. During later Quaternary time, interglaciations have been relatively short. Periods during which conditions were as warm as the present appear to last, on average, about 15–17 ka, before a decline begins that is the precursor to a new glaciation.

Global climatic signals at orbital frequencies have been detected and confirmed in other contexts, most notably in Antarctic and Greenland ice cores (EPICA Community Members, 2004; Masson-Delmotte et al., 2005), and in Chinese loess–paleosol sequences (Sun et al., 2006). It seems evident that astronomical cycles will continue to exert a strong influence on the Earth's climate and that the present interglacial period will, in due course, be succeeded by the next glaciation. Indeed, some believe that the next glaciation may have already begun (e.g., Ruddiman, 2003; Ruddiman, 2005).

Short-Term ('Sub-Milankovitch') Climatic Variations

Climatic perturbations that occur over much shorter frequencies cannot be explained by the astronomical cycles alone.

Figure 1 Stable oxygen isotope variations in marine cores spanning the last 2 My. The values are shown as deviations from a long-term mean. Variations in the marine isotope ratio reflect variations in the volume of global land ice, and hence the curve is primarily a 'paleoglaciational' curve, and only indirectly a paleoclimatic curve. Interglacial stages are shown in yellow, and glacial stages in blue. (See Lowe, 2001; Lowe and Walker, 1997 for further details.)

Short-term perturbations in the global climate system are most clearly reflected in cores obtained from the polar ice sheets (Alley, 2000). During the 1960s, several deep boreholes were drilled in Greenland and Antarctica, while a number of smaller ice masses in other parts of the world were also investigated. These pioneering studies showed that important paleoenvironmental information could be obtained from the analysis of stable isotope ratios, gas content, chemicals, and other impurities in ice that had accumulated over many thousands of years. Subsequent work in Greenland in the 1990s, most notably the GRIP and GISP-2 projects (Alley, 2000), and more recently, the NGRIP programme (2003), built on the previous research findings and provided penetrating new insights into recent global environmental change over the last glacial–interglacial cycle (NorthGRIP Members, 2004). In Antarctica, lower rates of snow accumulation mean that the ice-core sequences are generally stratigraphically less well-resolved than in Greenland, but there the record extends over a much longer time. The EPICA core, which is still being drilled, now extends back ~800 ka and may eventually reach 1 My (EPICA Community Members, 2004). The polar ice cores also contain a history of long-term stable isotope variations that generally match those obtained from marine cores that span the same time intervals. This indicates that the oceans and ice sheets are closely linked ('coupled') in both physical state and behavior. Mathematical models explain the exchange of stable isotopes between the oceans, the atmosphere, and the cryosphere, which are the dominant global reservoirs constituting the hydrosphere (Jouzel et al., 1987). The stable isotope and other proxy records reveal patterns of climate change at both Milankovitch and sub-Milankovitch (short-term) frequencies. Millennial and submillennial climate variations are clearly recorded in the Greenland ice-core records. The central sector of the Greenland ice sheet

is ~1500 m thick and provides a continuous environmental sequence extending over more than 100 ka. The precise period represented is uncertain due to deformation and thinning of the basal ice layers, but conservative estimates place the minimum age of the basal ice at ~123 ka (NorthGRIP Members, 2004). Distinctive annual layers occur in the upper levels of the core sequence, which means that past environmental changes can be resolved at a very high resolution, far higher than is normally achievable with marine- or lake-sediment records. An irregular series of peaks and troughs in the isotope signal (referred to as Dansgaard–Oeschger oscillations, after two leading ice-core scientists, Willi Dansgaard and Hans Oeschger) is replicated almost exactly between the GISP-2 and GRIP cores, and is equally well matched in the more northerly NGRIP core (Figure 2). The remarkable degree of conformity between these three records suggests that the ice sheet as a whole responded cyclically to hemispherical climatic forcing, the shifts in the stable isotope record reflecting a combination of changes in ambient temperatures, moisture source and delivery, and wind strength and direction. Notable features of this high-resolution paleoclimatic record include the following:

1. Modern isotope–temperature relationships suggest that the amplitude of isotopic variations represented in the Greenland ice-core records reflects shifts of up to 15 °C in ambient temperature during the last cold stage.
2. During the last cold stage (115–11.5 ka), as many as 27 distinct warming events (interstadials) occurred, some with maximum temperatures that approached, but did not quite reach, modern temperature values over central Greenland.
3. The climatic oscillations throughout the last cold stage, as reflected in the stable isotope records, typically range

Figure 2 Stratigraphic variations in the NorthGRIP core spanning the period ~9 ka (1400 m depth) to 120 ka (3200 m depth). The lowest curve shows variations in stable oxygen isotope ratios, the key proxy that reflects temperature variations over central Greenland. The middle panel shows variations in visible stratigraphy (ice color and transmissivity), while the top panel shows variations in dust concentration in the ice. The red dotted lines emphasize the antiphase relationships between oxygen isotope variations and dust concentration. Numbers in the lower panel indicate sequence order of abrupt warming events (interstadials). Reproduced from Svensson A, Nielsen SW, and Kipfstuhl S, et al. (2005) Visual stratigraphy of the North Greenland Ice Core Project (NorthGRIP) ice core during the last glacial period. *Journal of Geophysical Research* 110(D02): 108.

between 500 and 2000 years in duration, and the isotopic profiles show characteristic asymmetric shapes reflecting abrupt warmings that are followed by more gradual cooling trends.

4. In the upper layers of the ice cores, the duration of the transitions from cold stadial intervals to maximum warmth can be estimated by ice-layer counting; remarkably, the evidence indicates that some of these marked climatic shifts have occurred within a few decades (i.e., within a modern human lifetime), while the most recent major warming, marking the start of the current interglacial period at ~ 11.7 ka, may have occurred over an even shorter interval.

Collectively, the ice-core data suggest a considerable degree of instability in Greenland climate during the last cold stage, with oscillations between stadial and interstadial modes, a process that Taylor et al. (1993) likened to the operation of a 'flickering switch.' Prior to the publication of these records, climatic shifts of this magnitude and over such restricted timescales were not considered feasible. Two questions arose: (1) Were these climatic oscillations confined to Greenland? (2) What mechanism might cause the signal to flicker in this way? Subsequent research has shown that the ice-core climatic record for the last cold stage is not unique to Greenland, for similar climate histories have been discovered in other areas of the world. The answer to question 2 lies in the deep oceans where changes in ocean circulation appear to be the principal forcing factor in the operation of the climatic switch.

The Role of the Oceans

Shortly before the publication of the GISP-2 and GRIP ice-core results, Heinrich (1988) drew attention to a series of coarse sediment layers (now termed 'Heinrich Layers') in cores obtained from the floor of the North Atlantic. These are believed to be the products of glacier-calving around the margins of the northern ice sheets, which resulted in massive 'armadas' of icebergs in the North Atlantic circulating in a counterclockwise flow (gyre) and releasing sediment (ice-rafted debris) as they melted (Hemming, 2004). Eight such 'Heinrich events' occurred between 70 and 10 ka, indicating periodic and large-scale instability of the ice-sheet margins during times of maximal expansion. A close relationship was detected between episodes of coarse sediment influx into the North Atlantic, abundance of cold-adapted marine microfossils, and isotope variations in the GRIP record (Bond and Lotti, 1995; Figure 3). Hughen et al. (1996) presented compelling evidence for an even closer match between sediment variations in the tropical Atlantic and the GISP-2 record (Figure 4). Since then, geological archives from places as widely scattered as China, the Arabian Sea, and the sub-Antarctic have yielded proxy climate data that closely resemble oceanographic and climatic changes reflected in the North Atlantic records (e.g., Hemming, 2004; Porter and Zhou, 2006; Sachs and Anderson, 2005).

Several important points that have a bearing on our interpretation of the glacial record and of the global climate sequence arise from this work:

Figure 3 Variations in concentration of coarse mineral grains (lithic particles) and in abundance of the cold-adapted plankton species, *N. pachyderma* in sediment cores recovered from the floor of the North Atlantic, compared with the stable oxygen isotope record from the GRIP ice-core record. Reproduced from Bond GC and Lotti R (1995) Iceberg discharges into the North Atlantic on millennial timescales during the last glaciation. *Science* 267: 1005–1010.

Figure 4 Comparison between variations in sediment optical properties (light reflectance) of a laminated sequence of marine sediments in the Cariaco Basin, north of Venezuela, and the GISP-2 stable oxygen isotope record for the past 90 ka. Gray-shaded vertical bars represent Greenland interstadial events. Reproduced from Hughen KA, Overpeck JT, Peterson LC, and Trumbore S (1996) Rapid climate changes in the tropical Atlantic region during the last deglaciation. *Nature* 380: 51–54.

1. It is now clear that the history of glaciation is far more complex than was previously realized. Traditional models of glacier/ice-sheet advance and retreat have been based on painstaking investigation of continental records, but the evidence on land is partial simply because more recent glacier advances tend to bury or destroy the evidence of earlier glacier activity. The glacial-geological evidence from the last glaciation, for example, does not provide evidence of all the numerous stadial-interstadial oscillations that are reflected in the ice-core records.
2. The close correspondence between the isotope signal from Greenland and that from the sedimentary record in the North Atlantic suggests that the ice sheet and oceans were responding to the same external stimulus during the course of the last cold stage.
3. The often-abrupt climatic oscillations of the last cold stage were not confined to Greenland and the North Atlantic, but appear to have occurred in other parts of the world as well.
4. It is frequently assumed, although it has not yet been tested satisfactorily, that these abrupt climatic changes occurred more-or-less simultaneously on a global scale, and that major shifts in climate somehow operate contemporaneously.

A number of explanations have been put forward to account for the periodic instability of the ice sheets. These include self-regulating processes that came into play as the ice sheets became large enough to influence their immediate environment, by increased melting at the base, by extending into deeper water where marginal calving would be accelerated, or by some complex interplay between these factors and concomitant changes in global sea level. It has also been suggested that the timing of the onset of the Greenland interstadial events during the last cold stage approximates a 1.47 ky climate cycle

and hence ice-sheet instability could, in part, be a response to a more regular forcing mechanism such as solar variations (e.g., Schulz (2002)). Others, however, favor a different explanation, namely changes in the rate or pattern of ocean circulation.

One of the most persuasive advocates of the latter hypothesis is Broecker (1994) and Broecker (1997), who cites in its support the considerable body of paleoceanographic evidence which shows that the oceans, and the North Atlantic in particular, experienced marked changes in salinity, density, and rate of water movement during the last cold stage. These must, in Broecker's view, have had a major impact on the speed and pattern of flow of the thermohaline circulation, the network of surface and deep-water currents that circulates ocean water around the globe (Rahmstorf, 2000). The present arterial flows, such as the Gulf Stream, are maintained by thermal and salinity stratification, which leads to warm salty surface water being transported northward across the North Atlantic where it cools, sinks, and forms a return southward-flowing deep-water current. This circulatory system, or 'conveyor,' keeps NW Europe warmer than other regions in the northern hemisphere at comparable latitudes, and also delivers moisture to the Greenland ice sheet and to the smaller ice bodies in Iceland, Spitsbergen, and Scandinavia. According to this hypothesis, rapid melting of ice sheets would have delivered enormous volumes of cold freshwater onto the ocean surface, and since this would be lighter (less dense), it would form a cap over the ocean, preventing sinking, and thereby reducing the pressure gradient that drives the conveyor. This, in turn would have led to a marked cooling in the North Atlantic and NW Europe, and a reduction in moisture supply to the Greenland ice sheet.

This explanatory mechanism has been widely favored, partly because it is based on the physical parameters that govern ocean-water movement, and partly because numerical

modeling of the North Atlantic shows how sensitive the three-dimensional circulation pattern is to changes in surface water fluxes (Rahmstorf, 1995; Stocker and Wright, 1991). In addition, quantitative estimates of the volumes of water released to the North Atlantic during ice-sheet wastage at the end of the last glaciation appear to provide adequate fluxes for major disruptions of the ocean circulation system (Clark et al., 2003; Teller et al., 2002). It also offers a plausible explanation for why ventilation of the deep ocean (exchange of waters, nutrients, and oxygen with surface waters) was periodically interrupted throughout the last cold stage (Bard, 2002). Finally, it might explain why sudden changes in climate in the North Atlantic were also experienced in other parts of the world.

What cannot yet be adequately explained by these inferred oceanographic changes, however, is the trigger mechanism for ice-sheet instability. In seeking a resolution to this problem, it may prove to be a mistake to focus solely on the ice sheets and the oceans, for there is now a growing body of evidence for the operation of other factors in controlling abrupt climate change.

Global Feedback Mechanisms

The ice-core records constitute an unparalleled archive for showing how the different components of the global environmental system interconnect. The gas bubbles locked in the ice, for example, provide an independent record of variations in atmospheric gas content, which enables a direct comparison to be made with the stable isotope records that reflect ambient temperature. The evidence reveals a very close correlation between atmospheric levels of carbon dioxide (CO_2), deuterium, and global temperature (Figure 5), a relationship that has stimulated wide public debate about the continued rise in greenhouse gases in the atmosphere, and the implications for future global climate (IPCC, 2001).

There is also a close relationship between isotopic variations and the dust content of polar ice, at both glacial-interglacial (Delmas, 1992) and stadial-interstadial scales (Svensson et al., 2005). Figure 2 shows how peaks in the record of dust flux to the Greenland ice sheet during the last cold stage coincided with stadial intervals (lighter isotope ratios), while abrupt warmings at the start of the interstades coincided with marked reductions in dust content. Clearly, the atmosphere was dustier during cold periods. This may partly reflect increased transport of wind-borne dust under a more vigorous atmospheric circulation regime from arid and semiarid areas such as western China. It may also be partly explained by a reduction in stabilizing vegetation cover in such regions, and partly by wind erosion of exposed seafloor during times of reduced sea level.

Many other processes and environmental fluxes contributed to, and were affected by, abrupt climatic change, but the cases of CO_2 and dust serve to illustrate how difficult it is to determine with present knowledge which agents and processes were the key initiators of change. The problems are threefold: (1) The majority of geological records cannot yet be dated with a precision sufficient to determine the order in which different components of the Earth system change. (2) The linkages frequently are mutually dependent. For example, a change in climate might lead to a change in the global carbon cycle, but the latter could equally result from the operation of nonclimatic factors, for example, from an increase in ocean biomass due to a change in nutrient supply. One consequence of this might be an increase in the rate of extraction of CO_2 from the atmosphere, which then becomes locked in the oceans (a process referred to as 'draw-down' of CO_2) and which might, in turn, impact on climate. (3) The same changes may sometimes be induced by the operation of opposing or quite different processes. The amount of dust entrained in the atmosphere could, for example, increase with a shift to colder

Figure 5 Composite records of variations in atmospheric CO_2 concentrations (upper panel) and deuterium ratios (a paleotemperature index – lower panel) in gas bubbles in Antarctic ice cores spanning the last 650 ka. The upper panel shows combined data from the Dome C (black dots), Vostok (blue) and Taylor Dome (green) ice cores, while the lower panel shows deuterium records for Dome C (upper, dark blue curve) and Vostok (grey-blue). Reproduced from Siegenthaler U, Stocker TF, and Monnin E, et al. (2005) Stable carbon cycle–climate relationship during the late Pleistocene. *Science* 310: 1313–1317.

conditions through a lowering of sea level and exposure of silty areas to wind erosion, or by an increase in the transport of dust to polar regions from arid and semiarid regions. A similar effect could result from a warming trend that led to a reduction in effective precipitation in some regions and the expansion of arid and semiarid zones.

Understanding the complex chain of feedback mechanisms that constitutes the global environmental system is one of the most challenging areas of Quaternary science, but given the problems of interpretation referred to above, such an understanding will be difficult to achieve. However detailed and diverse Quaternary paleoenvironmental records may be, they do not, in themselves, constitute tests of causation between multiple competing variables. What is needed is some basis for experimentation, where key variables can be controlled while others are deliberately varied (and, perhaps, exaggerated) in order to isolate those that are the most influential. This takes us into another area where considerable progress has been made in Quaternary science in recent years: numerical modeling.

Numerical Environmental Modeling

Over the past several decades, increasingly sophisticated numerical models have been developed that can simulate a range of natural processes operating at the surface of the Earth (Schellnhuber, 1999). They are based on mathematical descriptions of the behavior of, and interactions between, specified variables, each component or interaction being mathematically prescribed to obey the laws of physics. Some models are simple, being constrained to focus on a particular process or on the interaction between selected variables within a limited geographical area, as, for example, a hydrological model of water-balance changes in a river catchment (Kutzbach, 1980). More complex models, however, are designed to represent the operation of Earth systems at a global scale. The best known and most sophisticated are general circulation models (GCMs), which simulate the operation of the global climate system (McGuffie and Henderson-Sellers, 2001). The capabilities of numerical models have increased dramatically within the last few decades following major advances in computer power and speed, software design, and the tools used to measure and monitor the natural fluxes between global reservoirs. Increased national and international cooperation in model design and intercomparison has also been a significant factor.

Quaternary scientists have long appreciated the potential of numerical models for providing analogs of the Earth system under different climate states, and for helping to clarify the key mechanisms that drive environmental change. Important integrated research programs employing numerical modeling have included simulations of the conditions in the ocean at the Last Glacial Maximum (CLIMAP Project Members, 1976; CLIMAP Project Members, 1981), and an analysis of the effects of insolation variations and concomitant changes in surface conditions on global climate over the past 18 ka (COHMAP Members, 1988; Kutzbach and Guetter, 1986). These were important milestones in a developing collaboration between Earth scientists who generate the paleodata and the numerical modeling community. The relationship has been reciprocal with, on the one hand, Quaternary scientists learning from

the modelers about the types of input data that are needed to generate the best model results, while on the other, the modelers require snapshots of past environmental conditions (based on paleoenvironmental reconstructions) from the Quaternary science community to test model outputs (van Andel, 2002). The latter are especially important because models are simplifications of the natural world with built-in assumptions. Hence, model outputs invariably have large uncertainties. Nowhere is this more apparent (or relevant) than in the current debate centering around the wide divergence in predictions of the nature and magnitude of future climate change generated by different GCMs (e.g., Allen et al., 2000).

One possible means of testing whether a GCM captures realistic climate situations, therefore, is to use the model to 'predict' an outcome for which an independent estimate already exists: this can be done by generating model evaluations of climate states for times in the recent geological past. In this procedure, a time period is selected for which the global boundary conditions are reasonably well known, and for which a detailed paleorecord can be compiled. The paleodata provide the basis for a reconstruction of the climatic conditions that may have prevailed at that time, and the model can be run to generate a stable climate state when forced by the prescribed (past) boundary conditions (e.g., Wright et al., 1993). The two outcomes can then be compared. One problem, of course, is that any significant differences between the results would be difficult to reconcile, for there is no independent means of determining the extent to which either, or both, are in error. Nevertheless, model data comparison is widely practised (e.g., Paleoclimate Modeling Intercomparison Project (PMIP) – <http://www-lsce.cea.fr/pmip/>), for there is a widespread view that improvements in both model design and in the amount and quality of the paleodata being generated will ultimately lead to greater convergence between the two outputs.

Numerical modeling plays an increasingly important role in contemporary Quaternary science because it permits speculative questions to be posed with some basis for constraining the answers provided. The balance between variables and inputs can be deliberately altered within a model in order to evaluate the nature, magnitude, and timing of environmental response. This approach has a range of applications. One example is the recent use of a GCM, forced by the insolation cycle alone, to examine future climate trends (Hargreaves and Annan, 2002). This particular model suggests that the Earth will experience a significant cooling step, followed by a slower cooling trend that will culminate in the next glacial maximum in about 60 ka. It also predicts that any 'global warming' effect caused by anthropogenic pollution will arrest this trend for about 30 years, but is unlikely to be large enough to prevent long-term cooling thereafter. A second example predicts the mass balance changes of the polar ice sheets and the subsequent effects on global sea level (Vaughan and Spouge, 2002), a topic of considerable concern given that a large percentage of the world's population lives within a few meters of present sea level. A third is the use of a three-dimensional ice-sheet model to examine the hypothesis that periodic large-scale oscillations of the North American Laurentide ice sheet may have been responsible for Heinrich events (Papa et al., 2006).

Although numerical modeling has provided important new insights into the workings of the global climate system, even

the most sophisticated of models have limitations. Some of the main areas of concern are the following:

1. Models invariably (and inevitably) oversimplify environmental complexity, for they cannot represent every component and synergistic interaction that occurs in nature. New discoveries continue to show how small-scale processes, such as feedback mechanisms involving cloud formation, can have far bigger impacts on climate (and also model output) than might have been anticipated (Williams et al., 2006).
2. Because numerical models can only handle a finite number of calculations, all the global processes and interactions represented in the models must be scaled down in order to be manageable. This inevitably leads to a 'scaling-up' problem when it comes to interpreting the output: this is the reverse logic problem of knowing whether the scaled-down, almost artificial microcosm, created in the model truly reflects the real operation of the system at the global scale.
3. Interactions between global subsystems (the atmosphere, hydrosphere, cryosphere, biosphere, geosphere) are invariably nonlinear. Hence, whereas it may be possible to predict responses within a simplified subsystem when only a few variables are involved, the greater the number of variables, the greater the complexity in terms of links between different subsystems. This almost inevitably means that the outcomes are less predictable (Clark et al., 1999; Rind, 1999).
4. Only very small changes in one or more parameters can have significant effects on model output. Running the same model twice using exactly the same parameters and boundary conditions can generate quite different outputs. Therefore, the outcomes may be unpredictable (Sivakumar, 2004), which may help explain why GCMs often tend to produce quite different predictions of future climatic scenarios.

Paradoxically, however, if an element of chaotic behavior is involved in all natural processes, then the only viable way forward in the search for an understanding of the global climate system, and predicting its behavior, is through numerical modeling. If this challenge is to be met, future generations of numerical models must become even more sophisticated. They will have to incorporate a much wider range of variables and linkages to reflect more realistically the complexity of the Earth system.

Climate and Humans

Concern over the modern climate-warming trend and the extent to which it may have been generated by human activity has stimulated widespread debate. The degree of concern over this issue is reflected in the tenor of the policy statements drawn up by almost every national government, as well as the increasing acceptance of the need for agreed protocols to curb greenhouse gas emissions. By far the most compelling evidence has been provided by Antarctic ice cores, which contain a detailed record of atmospheric gas ratios stretching back over the past 650 ka. Figure 6 shows the record of variations in concentration of atmospheric CO₂ and CH₄ over the past

Figure 6 Record of CO₂ (blue curve) and CH₄ (red) variations in the Vostok (Antarctic) ice core over the past 400 ka and projected future levels based on IPCC estimates. PAGES web resources: <http://www.pages.unibe.ch/about/index.html>.

400 ka obtained from the Vostok ice core (Petit et al., 1999). These data, together with the longer records from a second Antarctic borehole, Dome Concordia (Figure 5), indicate that natural atmospheric levels have normally been well below 300 ppm for CO₂ and 800 ppb for CH₄. The concentration of these greenhouse gases in the modern atmosphere is significantly above these levels (double in the case of CH₄), with the evidence pointing to a steady rise in concentrations from the time of the Industrial Revolution. However, it is the abrupt increase over the course of the second half of the twentieth century that gives the greatest cause for concern. Although the causal connections between atmospheric gas concentration and global temperature change continues to be a matter of dispute (e.g., Mann et al., 1998; McIntyre and McKittrick, 2003), there is a widespread acceptance that the late twentieth century warming detected in a range of proxy and instrumental records is anomalous (Osborn and Briffa, 2006), and that this is inextricably linked to increased atmospheric concentrations of greenhouse gases.

This view is reinforced by predictions, based on GCMs, of the likely atmospheric concentrations of these gases in ad 2100, should current fossil fuel consumption be allowed to continue unchecked. These values (Figure 6) are far in excess of

any recorded in the recent geological record. Should these predictions prove to be anywhere near reliable, then it is difficult to imagine that global climate will remain unaffected. Whether this will prove to be as detrimental to humans as is frequently predicted is difficult to assess, for there are no analogs in the Quaternary geological record for a world with climatic boundary conditions comparable to those of the present time having such high concentrations of atmospheric greenhouse gases.

The history of human impact on climate may, however, predate the Industrial Revolution, for it has recently been suggested that anthropogenically enhanced emissions of greenhouse gases (notably CO₂ and CH₄) could have begun as early as 8 ka as a result of the spread of deliberate burning of vegetation and the adoption of animal husbandry, cultivation, and other farming practices (Ruddiman, 2003; Ruddiman, 2005). Ruddiman's analysis of the natural rhythm of climate variations during the Quaternary leads him to conclude that if it were not for the present abnormally high levels of atmospheric CO₂ and CH₄, global climate would be ca. 2 °C cooler than it is today, and the world would be about a third of the way towards full glacial conditions (Ruddiman et al., 2005). Whether or not these conclusions are valid, they are examples of the types of question that are now being posed about the Earth's past and future climatic history, and it is in the rich archive of the Quaternary geological record where answers to such questions perhaps can be found best.

This article is a revision of the previous edition article by G.H. Miller and S.J. Clarke, volume 1, pp. 41–52, © 2007, Elsevier B.V.

Amino acids are simple organic molecules that are the fundamental building blocks of all proteins. Although there are a large number of possible amino acids, only approximately 20 are common constituents of proteins. Amino acids are assembled in long chains, in which they are linked by peptide bonds. Except for glycine, one of the simplest forms, all protein amino acids have at least one asymmetric carbon atom or center of symmetry. Such molecules are considered chiral molecules (derived from the Greek word for ‘hand’). Chiral molecules exhibit ‘handedness’ in that their mirror images are not superimposable (**Figure 1**). Consequently, they can exist in at least two different configurations or enantiomers.

Chiral forms of the same amino acid were originally identified by the way in which they rotated plane-polarized light passed through a solution containing the pure enantiomer. Enantiomers rotating the light to the left are designated L-amino acids (levorotatory), whereas those enantiomers rotating the light to the right are D-amino acid (dextrorotatory). For reasons that remain debated, life is left-handed, and almost all living organisms utilize exclusively L-amino acids to build protein. However, once biological constraints are removed upon the death of an organism, diagenetic reactions begin to degrade proteinaceous residues into their constituent amino acids, which spontaneously interconvert to their D-configurations in a regular and predictable manner. The process whereby an L-amino acid interconverts to its D-configuration is known as racemization.

Philip Abelson, working at the Carnegie Institution of Washington’s Geophysical Laboratory, was the first to recognize that amino acids could survive for millions of years at ambient Earth conditions, and that their unique initial status of 100% left-handed configuration offered the potential of

using amino acid racemization (AAR) as a geological clock or dating technique ([Abelson, 1954](#)). The first application of AAR as a dating tool was by Ed Hare, working with Abelson in the late 1960s ([Hare and Abelson, 1968](#); [Hare and Mitterer, 1967](#)). Early reviews of the application of AAR to geological dating are provided by [Schroeder and Bada \(1976\)](#) and [Williams and Smith \(1977\)](#). Recent reviews include [Johnson and Miller \(1997\)](#), [Kaufman and Miller \(1992\)](#), [Miller and Brigham-Grette \(1989\)](#), [Murray-Wallace and Kimber \(1993\)](#), [Wehmiller \(1990\)](#), and [Wehmiller and Miller \(2000\)](#), as well as two edited volumes focusing on the chemistry of amino acids in geological environments ([Goodfriend et al., 2000](#); [Hare et al., 1980](#)).

Factors Influencing the State of Biomolecules over Geologic Time

Amino acid geochronology belongs to the chemical family of dating methods. Chemical methods differ from radioactive dating techniques in that their reaction rate depends on one or more environmental parameters, whereas radioactive decay remains constant regardless of environmental conditions. The rates at which proteins are degraded and their constituent amino acids altered, the processes fundamental to amino acid geochronology, are primarily dependent on the temperature the samples have experienced. Consequently, the extent of any particular chemical alteration of amino acids depends on the time elapsed since the death of the organism and the integrated thermal history, and to a lesser extent in most settings on environmental pH, and vital effects unique to each taxon.

Figure 1 The structure of a generic amino acid and the mirror-image relation of its two stereoisomers or enantiomers.

Preservation of Amino Acids

The idea that amino acids might be preserved in biominerals over long periods of geological time was first proposed by [Abelson \(1954\)](#), who reported that the amino acids most stable at high temperatures in the laboratory were also present in fossils, the oldest of which was a 360 million-year-old Devonian fish. [Hare and Abelson \(1968\)](#) were able to separate L-isoleucine from its epimer, D-alloisoleucine, and they showed a correlation between the ratio of these epimers and time since the death of the organism. Subsequently, [Hare and Mitterer \(1969\)](#) demonstrated that changes in the amino acid composition of mollusk shells over geological time could be induced in the laboratory by heating, implying that the diagenesis of amino acids took place systematically. Supported by this observation, these authors were the first to estimate an age for a fossil based on the extent of AAR.

Amino acids are preserved in the geological record if they fail to enter the biotic nitrogen cycle. The nitrogen of polypeptides represents the major pool of organic nitrogen readily utilized in the biosphere. Without biological attack, the simplest amino acids are stable at ambient Earth surface temperatures for hundreds of millions of years. A common environment for the preservation of amino acids is the carbonate skeleton of invertebrates such as mollusks and Foraminifera. Organic material is incorporated into carbonate exoskeletons either between the mineral crystals (intercrystalline), where it usually has a role in determining the form and shape of the mineral phase during precipitation, or within crystals (intracrystalline), where it may serve to provide resiliency to the mineral phase.

Diagenesis refers to reactions that degrade organic molecules and their constituent amino acids during their residence in geological environments following the death of the host organism or its disuse of the molecules (e.g., avian eggshell proteins). Ultimately, the original complex proteins are degraded into simple hydrocarbons and nitrogen compounds. The organic residues present in fossils are not proteins in a biochemical sense but are commonly referred to as indigenous protein residues, reflecting their biological origin. In nearly all

Figure 2 Characteristic trajectory of increasing D-alloisoleucine/L-isoleucine (A/L) with increasing isothermal heating time of a modern biomineral, in this case a modern eggshell of the Australian emu heated at 143 °C. Modified from Miller GH, Hart CP, Roark EB, and Johnson BJ (2000) Isoleucine epimerization in eggshells of the flightless Australian birds, *Genyornis* and *Dromaius*. In: Goodfriend G, Collins M, Fogel M, Macko S, and Wehmiller J (eds.) *Perspectives in Amino Acid and Protein Geochemistry*, pp. 161–181. New York: Oxford University Press.

situations, when a biomineral enters the geological environment, all of its amino acids are in the L-configuration; this defines the starting point of the geological clock.

Amino Acid Racemization

Racemization is the chemical reaction that interconverts an amino acid from one molecular arrangement into its alternative enantiomer or mirror-image form ([Figure 1](#)). The rate at which racemization proceeds varies between amino acids according to the ability of R groups to stabilize a carbanion intermediate. The carbanion intermediate is the molecule formed when the hydrogen side chain is abstracted from an amino acid. In an ideal system, upon readdition of the hydrogen atom to the carbanion intermediate, there is an equal probability of L- and D-amino acid formation, and the forward and reverse reaction rates are equal. Under these conditions, D/L proceeds from values near zero in modern tissues until D/L reaches unity at racemic equilibrium. Because the reaction is reversible, a consequence of these conditions is the slowing of the apparent racemization rate as the extent of racemization increases – the characteristic curvilinear trend produced when D/L ratios are plotted against linear time ([Figure 2](#)).

Not all amino acids are suitable for geochronology. Glycine, the simplest and one of the most common amino acids, is not a chiral molecule. Other simple amino acids, such as alanine, are created in fossils by the decomposition of other more complex amino acids. Thermodynamically unstable amino acids, such as serine and threonine, have half-lives too short for most geological applications. The relatively slow-racemizing amino acids isoleucine, leucine, valine, and

Figure 3 Relation of D/L for aspartic acid (Asp) and glutamic acid (Glu) with respect to calibrated age in the ostracode *Candona* from deep lakes in the western United States. Gray envelopes denote $\pm 1\sigma$ uncertainty. Reproduced from Kaufman DS (2003) Dating deep-lake sediments by using amino acid racemization in fossil ostracodes. *Geology* 31: 1049–1052.

Figure 4 Possible racemization pathways for the protein amino acid L-isoleucine. In nature, nearly all of the L-isoleucine epimerizes to D-alloisoleucine.

glutamic acid are widely used in geochronology, as is the relatively fast-racemizing aspartic acid (Figure 3).

The amino acids commonly utilized for geochronological applications, with the exception of isoleucine, have a single chiral carbon atom and can exist in either their D- or L-forms, which have identical physical and chemical properties except in their interaction with other chiral substances. Isoleucine has two chiral carbon atoms and can racemize about either or both carbon atoms (Figure 4). In nature, L-isoleucine racemizes almost exclusively about the alpha carbon, producing a new molecule, D-alloisoleucine ('allo' meaning other). Because D-alloisoleucine is not a mirror image of L-isoleucine, it has

different chemical and physical characteristics, making it easier to separate in the laboratory. The reaction by which L-isoleucine converts to D-alloisoleucine is known as epimerization, and the extent of isoleucine epimerization is abbreviated A/I or alle/Ile. The equilibrium ratio of D-alloisoleucine to L-isoleucine of approximately 1.30 indicates the reverse reaction (D-allo formation) is 30% more likely than the forward reaction (L-Ile formation; Williams and Smith, 1977).

Temperature

Rates of AAR and most other diagenetic reactions, such as hydrolysis, deamination, decarboxylation, and condensation, are highly sensitive to temperature. The temperature dependency of these reactions is described by the Arrhenius equation:

$$k_1 = Ae^{(-E_a/RT)} \quad [1]$$

$$\ln(k_1) = \ln(A) - E_a/RT \quad [2]$$

where k_1 is the forward rate constant; A is a constant, often referred to as the Arrhenius factor; E_a is the activation energy; R is the universal gas constant; and T is the integrated thermal history T_{eff} in Kelvin.

The Arrhenius equation is derived empirically as the best fit to observed changes in reaction rates with respect to temperature. This is usually achieved by heating modern samples isothermally for specific time intervals in the presence of water vapor and determining the temperature-specific rate constant (k_1) for each temperature. In practice, this can be accomplished for temperatures between 80 and 160 °C. Lower temperature rate constants are usually derived from radiocarbon-dated samples in sites of near-constant temperature. Equation [2] indicates that plotting $\ln(k_1)$ against the reciprocal of its absolute temperature will define a straight line, with the activation energy directly proportional to the slope of the line and the Arrhenius factor defined by the intercept (Figure 5).

The rate constant, k_1 , is related to time (t , measured in years) by the integrated rate equation (Bada and Schroeder, 1972):

$$k_1 = \ln \left[(1 + D/L) / (1 - K'D/L) \right] \times \left[(1 + K')t \right]^{-1} + c \quad [3]$$

where $K' = k_2/k_1$; c is a constant to account for laboratory-induced racemization: $c = \ln[(1 + D/L_0)/(1 - K'D/L_0)]$; and D/L_0 represents the extent of racemization measured in a modern specimen (e.g., live at time of collection, equivalent to time zero, or the start of the geologic clock). For most amino acids the forward and reverse rate constants, k_1 and k_2 , are equal; therefore, $K' = 1$. For the interconversion of L-Ile to D-allo, $k_1/k_2 = 1.3$, and $K' = 0.77$.

The activation energies for racemization of most amino acids preserved in carbonate fossils are between 28 and 30 kcal mol⁻¹. This range implies that the reaction rate approximately doubles for every 4 °C increase in burial temperature at typical ambient temperatures (−10 to +30 °C). The effect of temperature on reaction rate is readily apparent in a plot of racemization levels for last interglacial 'moderate' racemization rate mollusks from the European Arctic to the Mediterranean (Figure 6).

Figure 5 Arrhenius plot for isoleucine epimerization in eggshells of *Dromaius*, the Australian emu, based on isothermal heating of modern eggshell at 160, 143, 126, 110, and 85 °C and radiocarbon-dated early Holocene specimens between 21 and 17 °C. Reproduced from Miller GH, Hart CP, Roark EB, and Johnson BJ (2000) Isoleucine epimerization in eggshells of the flightless Australian birds, *Genyornis* and *Dromaius*. In: Goodfriend G, Collins M, Fogel M, Macko S, and Wehmiller J (eds.) *Perspectives in Amino Acid and Protein Geochemistry*, pp. 161–181. New York: Oxford University Press, with permission.

The exponential dependence of reaction rate on temperature [eqn. [1]] places significant constraints on optimal geological contexts for samples. The T_{eff} experienced by a buried biomineral is strongly influenced by the magnitude of the temperature variations during the postdepositional interval. Consider a simple case. A fossil spends half of its time buried at a temperature of 0 °C and half at 20 °C. The arithmetic mean temperature is 10 °C, but the extent of racemization exhibited by the fossil would be the same as if it had been stored at a constant 16.7 °C for the entire time, dramatically higher than the arithmetic mean temperature (Figure 7). For this reason, racemization temperature is defined as the effective diagenetic temperature (T_{eff}). T_{eff} is the equivalent temperature required to explain the extent of observed racemization if the sample had experienced a constant postburial temperature. It is always equal to or higher than the arithmetic mean temperature.

Sites with high diurnal or seasonal temperature fluctuations will have T_{eff} well above the arithmetic mean temperature. In most environments, samples only need to be buried a few centimeters to escape the diurnal heating cycle, but the seasonal cycle in continental climates, although rapidly damped, can extend to a depth of several meters. Reactions monitored at a continental site in southern New Mexico exhibit a seasonal temperature amplitude over 20 °C in the upper few centimeters, resulting in an T_{eff} more than 10 °C above the mean annual air temperature (MAT; Figure 8). The amplitude of

Figure 6 D-alloisoleucine/L-isoleucine (A/I) in moderate racemization rate mollusks from last interglacial (~125 ka) sites across western Europe, ranging from Svalbard and Arctic Russia to the Mediterranean Basin, plotted against current mean annual site temperature. Last interglacial sites are dated by U/Th on corals or correlated to the last interglacial on the basis of diagnostic marine faunal elements. These data document the close correlation to and exponential dependency of racemization rate to site temperature. Unpublished data from G. H. Miller and P. J. Hearty, University of Colorado.

Figure 7 A simplified illustration of the impact of variable burial history. A fossil is buried for equal time at 20 and 0 °C. The arithmetic mean temperature is 10 °C. However, because of the exponential dependency of racemization rate on temperature, the fossil will exhibit the same amount of racemization as a sample maintained for the same total time at a much higher temperature (16.7 °C). This is the effective diagenetic temperature (T_{eff}).

Figure 8 The difference between effective diagenetic temperature (T_{eff}) and mean annual air temperature (MAT; mean, 16.8 °C) with depth based on multiyear instrumentation of a strongly continental site in southern Arizona. The relatively high amplitude of the annual temperature cycle near the surface ($T_{\text{amp}} = 21$ °C) results in an T_{eff} 9 °C above the MAT. The predicted A/I in a gastropod held at specific depths for 14 ka is plotted on the By a depth of approximately 1 m, the difference between predicted and expected A/I is within analytical uncertainties, but at shallow burial depths the predicted A/I deviates sharply from that expected based on the site MAT. Modified from Miller GH and Brigham-Grette J (1989) Amino acid geochronology: Resolution and precision in carbonate fossils. *Quaternary International* 1: 111–128.

the annual temperature cycle decreases rapidly so that by 2 m depth it is <6 °C, at which point the difference between T_{eff} and MAT is negligible (<1 °C; **Figure 8**).

Sampling strategies must recognize the importance of avoiding high-amplitude temperature fluctuations. In exposed continental sites, collecting sites should have been buried 2 m or more for most of their postdepositional history. Shaded sites and sites from more maritime regions need not be so deeply buried.

Environmental pH

Racemization is known to be strongly base catalyzed (e.g., **Smith et al., 1978**), and biominerals heated in solutions above pH 9 racemize more quickly than do the same biominerals heated at neutral pH. For example, Asp D/L values were 29% higher in mollusk shell heated in pH 10 solution compared with pH 7, and Glu D/L values were 134% higher (**Figure 9**; **Orem and Kaufman, 2011**). The proportion of free amino acids in the laboratory-heated shells also increased with increasing pH, as did the rate of removal of amino acids from

Figure 9 Rate of racemization for aspartic acid, and glutamic acid in *Margaritifera* shell heated in buffered solutions with pH ranging from 7 to 10. Shells were heated at 110 °C for up to 160 h. Rates of racemization increase with increasing pH. Curves are simple logarithmic (Asp) and power (Glu) fits. Data from **Orem and Kaufman (2011)**.

the shell matrix (leaching). A similar experiment using ostracodes showed that the D/L values and amino acid concentrations were higher in valves heated in pH 10 buffer than in valves heated in pH 7 buffer (**Bright and Kaufman, 2011a**). Carbonate fossils have the advantage of buffering ambient pH and maintaining a local environmental pH of ~8. Samples from strongly basic environments (pore fluid pH > 9) should be avoided.

Taxonomic Effects

Position in a Polypeptide Chain

The negative correlation between the molecular weight of polypeptides and the extent of racemization among their amino acids is a product of the relation between the racemization rate of an amino acid and its location within the polypeptide. For example, the extent of isoleucine epimerization in various molecular fractions of three *Genyornis* eggshells is always lowest in the highest molecular-weight fraction, whereas the

Figure 10 Extent of isoleucine epimerization (alle/Ile) measured in four molecular-weight fractions of four late Pleistocene eggshells of the extinct giant Australian bird, *Genyornis*. Alle/Ile was measured in high-molecular-weight (HMW), moderate-molecular-weight (MMW), low-molecular-weight (LMW), and free (FREE) fractions. In all four samples, alle/Ile increased with decreasing molecular weight. Symbols on the right are alle/Ile in the total acid hydrolysate. Modified from Kaufman DK and Miller GH (1995) Isoleucine epimerization and amino acid composition in molecular-weight separations of Pleistocene *Genyornis* eggshell. *Geochimica et Cosmochimica Acta* 59: 2757–2765.

low-molecular-weight and free amino acid fractions have the highest *A/I* values (Figure 10; Kaufman and Miller, 1995). Laboratory experiments indicate that amino acids located at interior positions within peptide chains feature low rates of racemization, whereas amino acids located at terminal positions and incorporated in diketopiperazines racemize most rapidly. The *D/L* of free amino acids is commonly high but the reaction rate is low when the molecules exist in this state. This potential incongruity is explained by the preferential release of relatively highly racemized amino acids from terminal positions into the free amino acid pool. Relatively intact polypeptides have a higher ratio of interior to terminal amino acids than smaller polypeptides; consequently, high-molecular-weight separations feature a lower extent of racemization.

The differences in racemization rates produce two pools of amino acids with different average *D/L* that are readily separated: 'free' and 'total acid hydrolysate.' Normally, peptide bonds are hydrolyzed prior to amino acid analysis by heating the decalcified residue (typically 22 h at 110 °C) in a strong acid (6 N HCl) to yield the total acid hydrolysate fraction. Alternatively, the unhydrolyzed residue, or free fraction, is dominated by naturally hydrolyzed amino acids. Due to the more advanced level of racemization in this pool, *D/L* in the free fraction may provide a more effective means of separating intervals of time than is attainable with *D/L* in the total acid hydrolysate.

Figure 11 (Top) Typical intrashell variability in *A/I* – in this case, in a last interglacial age marine taxodont *Glycymeris* from the Mediterranean. (Bottom) A cross section through a marine pelecypod, showing how growth bands extending to the surface can serve as pathways that allow leaching of low-molecular-weight organic compounds. The optimal sample site in both examples is an inner layer, near the umbo region ('A' and 'B' in the top panel), where the shell is dense and there are fewer pathways for leaching.

Optimizing Sample Sites Within a Fossil

Many fossils, including mollusks and eggshells, have different structural layers. Usually, each structural layer contains a different suite of amino acids. Because the racemization rate for any specific amino acid depends to some extent on the nature of its bonds with adjacent amino acids in its peptide chain, racemization rates commonly vary in different structural layers. Consequently, sampling should be restricted to a single layer.

Tests of mollusk *A/I* variability indicate values may differ by up to 40% in different parts of even relatively simple bivalves (Figure 11, top). In bivalve shells, most of the protein residues reside along intercrystalline growth, where they act to nucleate incremental shell growth. Leaching of amino acids and small peptides is enhanced where these growth bands intersect the surface of the shell (Figure 11, bottom). Consequently, optimal sampling sites for AAR studies are located at sites 'A' or 'B' in Figure 11 (top).

Other Vital Effects

Differences up to a factor of 2 in racemization rates according to taxonomy have been noted for mollusks, Foraminifera, and avian eggshells. Among mollusks, there are significant differences between genera but broadly comparable reaction rates among species of the same genus. The reason for the taxonomic dependency is not precisely known, but because they are accompanied by differences in amino acid composition, likely explanations are differences either in the amino acid composition of the precursor proteins or in the relative abundance of the numerous proteins involved in the secretion of these carbonate structures. For example, Goodfriend (1992) observed high concentrations and very rapid racemization of Asx residues in the coral *Porites australiensis*. Because peptide bonds at Asx sites are prone to hydrolysis, the authors interpreted these observations as cause and effect. Where multiple species are recovered in association, intergeneric differences in racemization rates provide an internal check on the reliability of D/L values. Similarly, because amino acids feature characteristic rates of racemization, a comparison of the D/L values of different amino acids within a sample provides an additional means of assessing the veracity of data.

Almost all biominerals contain a relative abundance of specific amino acids that are unique at the generic level. This characteristic signature can be used as a taxonomic tool and provides a test for impurities in most geological samples.

Leaching

The physical transport of amino acids out of mineral matrices by an aqueous phase, commonly water, is termed 'leaching.'

The rate of leaching is controlled by the size of the mobile molecules and their sorption to the fossil matrix, the diameter and complexity of the diffusion pathway, and temperature (Collins and Riley, 2000). Molecules most susceptible to leaching are the low-molecular-weight solutes (i.e., free amino acids, small peptides, and diketopiperazines) in which protein residues are situated in pathways that lead to the exterior of the biomineral. Because low-molecular-weight residues tend to be more racemized, leaching decreases the overall level of racemization. Hot, alternately wet and dry environments are most conducive to leaching.

Protein residues preserved in intracrystalline sites are least susceptible to leaching, and have been shown to approximate a closed system (e.g., Miller et al., 2000; Sykes et al., 1995). Isolating and analyzing this fraction of amino acids can improve the reliability of amino acid geochronology. Most studies of the intracrystalline fraction for Quaternary geochronology have focused on mollusks. Exposure of powdered mollusk shell to concentrated sodium hypochlorite (bleach) for 48 h effectively reduces the amino acid content to a residual level, assumed to represent the intracrystalline fraction. Penkman et al. (2008) showed that the shell-to-shell variability in D/L values for the intracrystalline fraction of a single-age population was reduced by 50% compared with conventionally analyzed shells, and the correlations between D/L values between free and hydrolyzed amino acids were increased (Figure 12). The effect of the same bleaching pretreatment on freshwater ostracodes (crustacean), however, is less clear. Bright and Kaufman (2011b) showed that bleaching had virtually no impact on the amino acid concentration or the D/L values in fossil ostracodes valves older than approximately 1 ka. Nor did the pretreatment reduce the intrasample variability. The proteins associated with the chitin-rich organic matrix of ostracode

Figure 12 Asx D/L values in the total hydrolysable amino acid (THAA) population versus Asx D/L in the free amino acid (FAA) population of the same shell for unbleached (left) and bleached (right) subsamples of *Bithynia* shells from marine isotope stage 7 and 9 deposits in the United Kingdom. Results of analyses on bleached shells (intracrystalline fraction) yielded greater consistency. Reproduced from Penkman KEH, Kaufman DS, Maddy D, and Collins MJ (2008) Closed-system behaviour of the intra-crystalline fraction of amino acids in mollusc shells. *Quaternary Geochronology* 3: 2–25.

valves appear to behave somewhat differently than in mollusk shells.

Separation and Detection of D- and L-Amino Acids

The separation, detection, and quantification of the D- and L-amino acid enantiomers and diastereomers are accomplished by either gas or high-pressure liquid chromatography (HPLC). L-Isoleucine can be separated from its D-alloisoleucine pair by conventional ion-exchange HPLC, which provides a quantitative assessment of most other protein amino acids and allows an independent assessment of sample quality. Most other D-/L-amino acid pairs are separated by gas chromatography or reverse-phase liquid chromatography using a chiral stationary or mobile phase to separate the enantiomers (Figure 13). An interlaboratory standard (Wehmiller, 1984) provides an independent check on instrumental accuracy.

Applications

AAR has potential application in the Quaternary sciences wherever amino acid residues are preserved over geological time and questions of time or temperature remain. To utilize AAR as a dating tool requires a medium that not only preserves indigenous protein amino acids from bacterial attack and

leaching but also excludes contamination by other amino acids. The more tightly the amino acids are integrated into the biominerals, the closer the medium will be to a closed system. Commonly utilized fossils include marine bivalves, land and aquatic snail shells, eggshells, Foraminifera, and ostracodes. Most are abundant in the geologic record and preserve amino acids well over geologically significant timescales. Other materials that have been analyzed, some with mixed success, include fish otoliths, woodrat middens, wood, bones and teeth, corals, and the carbonate spores of charophyte oögonia. Although most applications utilize amino acids derived from known biological sources, racemization studies in biogenic carbonate breccia (e.g., 'whole rock' eolianites), speleothems, and paleosols have proven successful.

The time interval over which racemization is effective is determined by the reaction rate: it is longer in cold climates (low rate) than in tropical climates (high rate). At room temperature (22 °C), conversion from an optically pure L-amino acid ($D/L=0$) to a racemic mixture lacking optical activity ($D/L=1.0$ for most amino acids) requires several tens of thousands of years for most amino acids. At 160 °C, a racemic mixture is reached within 10–20 h, whereas in Arctic regions (–10 °C) racemic equilibrium requires 1–2 Ma. The useful time range for dating under different mean annual temperatures for isoleucine epimerization (valine, leucine, and glutamic acid racemization have similar time ranges) is illustrated in Figure 14.

Aspartic acid racemizes approximately an order of magnitude faster than other amino acids and is frequently used for very young materials or extremely cold sites (Figure 3). In tropical settings, the rapid racemization of Asx residues provides age resolution for very young samples, whereas the slower epimerization of isoleucine is effective at distinguishing events that are thousands of years apart (Figures 3, 15, and 16).

Figure 13 Reverse-phase liquid chromatography chromatograms of single individuals of the large planktonic foraminifer *Pulleniatina* from marine cores recovered off northeastern Australia, with approximate ages of 100 ka (a) and 600 ka (b). Modified from Hearty PJ, O'Leary MJ, Kaufman DS, Page M, and Bright J (2004) Amino acid geochronology of individual foraminifer (*Pulleniatina obliquiloculata*) tests, north Queensland margin, Australia: A new approach to correlating and dating Quaternary tropical marine sediment cores. *Paleoceanography* 19: PA4022.

Aminostratigraphy

AAR can be applied as a geological dating tool in a relative and absolute sense. As a relative dating tool, the technique is

Figure 14 Relation between the extent of isoleucine epimerization (A/I) and sample age for T_{eff} between 0 and 25 °C showing the strong dependence of epimerization rate on temperature. Lines are derived from kinetics in eggshells of the Australian emu (*Dromaius*) shown in Miller et al. (2000), but the relation is generally applicable to most carbonate fossils.

known as aminostratigraphy. Aminozones, a chemostratigraphic unit based on clustering in the extent of AAR in replicate fossils, are the fundamental units of aminostratigraphy. The premise is that over a limited geographic range and elevation, samples experienced a similar thermal history (MAT, $\pm 1^\circ\text{C}$; temperature amplitude at collection site, $< 6^\circ\text{C}$). Over this limited region, samples with similar D/L are of the same age, those sites with higher D/L are older, and those with lower D/L are younger. Aminostratigraphy does not require an

assessment of racemization kinetics or estimates of past thermal histories, and it is the least ambiguous application of amino acid geochronology.

Aminostratigraphy has been applied to mollusks excavated from raised marine terraces in coastal regions throughout the world. One example is a series of uplifted interglacial terraces along the Peruvian coast from which bivalve mollusks exhibit a regular increase in D/L leucine in higher (older) terraces, with corresponding absolute ages derived from electron spin resonance (ESR) dating (Figure 17).

Figure 15 Fast-racemizing amino acids provide superior resolution for cold or very young samples. D/L aspartic acid and D-alloisoleucine/L-isoleucine (A/I) were measured in the marine bivalve *Hiatella arctica* collected from raised marine terraces along the north coast of Alaska (mean annual temperature, ca. -12°C). For the younger shorelines, D/L Asp provides a clearer separation of the sites, but this difference decreases for the older shorelines. Aminozones: mo, modern; Pe, Pelukian shoreline (last interglaciation); Wa, Wainwrightian shoreline; Fi, Fishcreekian shoreline; Bi, Bigbendian shoreline; and Co, Colvillian shoreline (probably late Pliocene). Modified from Goodfriend GA, Brigham-Grette J, and Miller GH (1996) Enhanced age resolution of the marine Quaternary record in the Arctic using aspartic acid racemization dating of bivalve shells. *Quaternary Research* 45: 176–187.

Absolute Age and Paleothermometry

Once the temperature-dependence of racemization in a particular biomineral has been derived, the equation describing racemization contains three unknowns: D/L (the extent of the reaction, which can be measured in the laboratory); t , the time since death; and T , the integrated thermal history. Theoretically, if either time (t) or effective diagenetic temperature (T) is known, the other can be predicted (from eqns. [1] and [3]):

$$Ae^{(-E_a/RT)} = \ln[(1 + D/L)/(1 - K'D/L)] \times [(1 + K')t]^{-1} \quad [4]$$

In theory, deriving absolute ages from the extent of AAR requires only an estimate ($\pm 1^\circ\text{C}$) of the T_{eff} . For samples of late Holocene age, this can be reasonably estimated from the instrumental record, but secure estimates for the time-dependent changes in MAT across glacial–interglacial cycles are rarely possible. Bada and Protsch (1973) presented an alternative approach in which an appropriate *in situ* value for k_1 is determined from the D/L ratio of a specimen of known age. This ‘calibrated’ rate constant may be used to determine the age of nearby specimens from their D/L value, assuming they have experienced a comparable thermal history. For Quaternary samples, a reasonable assumption is that a calibration site of

Figure 16 Examples of racemization applied to two very different timescales. D/L Asx in very young corals ((a) data from Goodfriend GA, Hare PE, and Druffel RM (1992) Aspartic acid racemization and protein diagenesis in corals over the last 350 years. *Geochimica et Cosmochimica Acta* 56: 3847–3850) and A/I in the giant clam *Tridacna* from the Huon Peninsula ((b) data from Hearty PJ and Aharon P (1988) Amino acid chronostratigraphy of late Pleistocene coral reef sites: Huon Peninsula, New Guinea and the Great Barrier Reef, Australia. *Geology* 16: 579–583). Note timescales differ by three orders of magnitude.

Figure 17 Schematic cross section through a flight of raised marine terraces on the coast of Peru with amino zones (in roman numerals) defined on the extent of leucine racemization. Electron spin resonance (ESR) dates provide additional chronological control. The highest terraces are of early Quaternary age. Modified from Wehmiller JF (1993) Applications of organic geochemistry for Quaternary research: Aminostratigraphy and amino chronology. In: Engel M and Macko S (eds.), *Organic Geochemistry*, pp. 755–783. New York: Plenum.

at least 100 ka has a T_{eff} that is a reliable estimate for most of the Quaternary.

Age estimates for many fossils can be complicated by kinetic uncertainties. An inherent assumption is that racemization follows simple, reversible first-order kinetics. Although this assumption is approximated during the early stages of racemization, most mollusk and Foraminifera shells deviate from predicted linear kinetics in the later stages of diagenesis. This has led several researchers to utilize empirically derived models (Figure 18) that more closely approximate the observed change in D/L with time.

In an evaluation of uncertainties, McCoy (1987) showed that predicting paleotemperatures is inherently more precise than predicting ages. Unlike most biological proxies that record the instantaneous temperature at which an organism lived, racemization-derived paleotemperatures reflect the integrated thermal history (T_{eff}) since the organism died. In the case of deeply buried samples, this equates to the integrated mean annual temperature. If samples with independently derived ages are available from a limited region, then the evolution of temperature across the region can be calculated. For example, the Pleistocene/Holocene temperature change in semiarid Australia was quantified from A/I in emu eggshells, each of which had also been dated by ^{14}C (Figure 19). Not all samples were deeply buried; hence, some samples exhibit more advanced levels of racemization than expected, but the change in slope between samples with the lowest A/I dated <16 ka and those >16 ka is unambiguous and reflects at least 7 °C warming from the cold Last Glacial Maximum to the warmth of the present interglacial.

Time-Averaging

A burgeoning application of amino acid geochronology is dating individual shell fragments that comprise fossil death assemblages. Such assemblages often comprise large collections of mixed-aged shells of one or more species. The temporal resolution of paleoenvironmental information that ultimately can

Figure 18 Cubic transformation of D/L Asx to linearize the original kinetics (inset), from which the slope is proportional to sample age. Original data from Goodfriend (1992) (land snails heated at 100 °C, open circles) and Brinton and Bada (1995) (free asparagines heated at 100 °C). Reproduced from Collins MJ, Waite ER, and van Duin ACT (1999) Predicting protein decomposition, the case of aspartic acid racemization kinetics. *Royal Society of London Philosophical Transactions, Series B, Biological Sciences* 354: 51–64, with permission.

Figure 19 A/I (in its linearized form) plotted against corresponding calibrated radiocarbon ages for 43 samples from central Australia. Asymmetric vertical error bars incorporate the possibility of shallow burial. Horizontal error bars reflect $\pm 1\sigma$ dating errors where the uncertainty exceeds the diameter of the plotted point. Regression lines, which are directly proportional to temperature, go through the lowest A/I . The lower slope for samples older than ~16 ka indicates much lower Pleistocene temperatures in central Australia than during the Holocene. Modified from Miller GH, Magee JW, and Jull AJT (1997) Low-latitude glacial cooling in the Southern Hemisphere from amino acids in emu eggshells. *Nature* 385: 241–244.

be derived from a fossil assemblage is determined by its range of ages (time-averaging). Biogenic carbonate fossil remains are known to survive extensive reworking and prolonged residence times at the sediment–water interface (e.g., Flessa and Kowalewski, 1994). The age distribution of shells provides important information about compositional biases in the fossil record that result from ‘filtering’ processes that are both taxon- and facies-dependent, including shell input and durability (Carroll et al., 2003; Kidwell et al., 2005; Kosnik et al., 2007). In addition, the ages of fossil assemblages provide baseline geohistorical data needed to understand the ecological and evolutionary response of species to environmental changes, the basis of conservation paleobiology (Dietl and Flessa, 2011).

Amino acid geochronology is a cost-effective approach to dating hundreds of shells with accuracy ranging from multi-decadal to centennial, depending on ambient water temperature and on the ability to accurately calibrate the rate of racemization. The basic procedure is to analyze many shells to determine the overall relative-age structure of the death assemblage. Multiple individual fragments distributed across the range of ages indicated by the D/L values are then targeted for accelerator mass spectrometry (AMS) ^{14}C analysis. The resulting relation between ^{14}C age and D/L is used to calibrate the rate of racemization for a particular taxon from a study area (Figure 20). The calibrated rate can then be applied to other shells whose ages were not determined by ^{14}C (e.g., Kosnik et al., 2008).

Because the aim of time-averaging studies is to determine the structure of the age distribution, any data screening must be

done cautiously and systematically. A broad range of screening criteria for identifying outliers and determining the suitability of specimens for numerical dating have been explored based on a large collection of mollusk shells of multiple taxa from a shallow-water core in the central Great Barrier Reef (Kosnik and Kaufman, 2008). The results show that some taxa provide higher-resolution temporal information than others, and highlight the importance of identifying the taxa that are likely to preserve the best geochronological information.

Conclusions

Amino acid geochronology offers a simple but powerful relative dating tool (aminostratigraphy) that provides temporal constraints on biominerals beyond the range of radiocarbon dating. The fast-racemizing Asx can be used to assess differences in age over a few decades to centuries in optimal settings, an interval over which radiocarbon calibration uncertainties are unusually large. In all but the hottest regions, the overall time range includes all or most of the Middle and Late Quaternary, a time window not readily dated by many other methods. When independent calibration is available, the extent of racemization can be used to reconstruct past thermal histories with a precision of $\pm 1^\circ\text{C}$. Also, with suitable calibration the extent of racemization can be converted to reliable absolute ages. Although the measured extent of racemization depends heavily on temperature, the racemization reaction does not involve the loss of reactants; hence, the measurement

Figure 20 AAR calibration curves for *Tellina* shells from Rib Reef, Australia (left two panels). Open squares represent ^{14}C -dated specimens (vertical line is the 2σ age range). Lines are best-fit linear regression and confidence intervals. Gray circles are AAR ages of shells. D/L values are transformed exponentially to linearize the trend. Right two panels compare racemization age of individual *Tellina* shells to their depth in two different cores. Median (bar), fiftieth percentile (box), and ninety-fifth percentile (whisker) are shown. Samples above 20 cm are younger than samples below the dashed lines. However, there is no clear age versus depth relation below 20 cm, suggesting deep, active bioturbation. Modified from Kosnik MA, Hua Q, Jacobsen GE, Kaufman DS, and Wüst RA (2007) Sediment mixing and stratigraphic disorder revealed by the age-structure of *Tellina* shells in Great Barrier Reef sediment. *Geology* 35: 811–814.

statistics for old samples are similar to those for young samples. For the most stable amino acids, the concentration of the summed D- and L-forms at racemic equilibrium is of a similar magnitude to the concentration of the original L-amino acid, providing there has been no diffusional loss from the biomineral matrix. Not all biominerals are optimal for amino acid geochronology. Those that approximate closed system behavior with respect to indigenous amino acids are optimal. This is usually met in samples for which the amino acids are sequestered within the crystal matrix of a fossil.

Introduction

The study of hominids, hominins, and humans ([Table 1](#)) in the Quaternary period is an interdisciplinary endeavour that combines the expertise of the biological, physical, human, and natural sciences ([Figure 1](#)). Scientific advances in this collective enterprise have been most marked in the past 50 years. They can be summarized by the appearance of a new subdiscipline, paleoanthropology, that emerged in the 1970s. The title includes, at a minimum, the following specialists: archaeologists, physical anthropologists, molecular geneticists, geochronologists, and paleoecologists. Paleoanthropologists are not only interested in investigating well-dated sequences that contain environmental and hominin data but also in using these archives to study the behavior of our earliest ancestors. They work in the wider framework of evolutionary models and principles. Their primary interests lie in using the current wealth of paleoenvironmental data to understand changing adaptations in the various hominin lineages, and using the continuous records of climate change, particularly those from the ocean and ice-core archives, to examine whether a forcing mechanism existed that explains

both anatomical and behavioral evolution. More recently, the field has developed an interest in the biogeography of hominins and in particular the timing of major dispersals and their explanation ([Straus and Bar-Yosef, 2001](#)).

The papers in this section address these and other themes in paleoanthropology on a geographical basis. The evidence is presented and assessed and a flavor of the common but distinctive traditions of regional and national research is provided. The date of 300 ka has been used to organize the archaeological evidence. This corresponds to the beginning of MIS8 in the marine record. This cold stage does not in itself mark an abrupt change either in hominin archaeology or anatomy, but after this date significant technical, cultural, and social changes occurred cumulatively, and especially during the Upper Pleistocene (MIS5-2).

The Transition to Paleoanthropology

The development of paleoanthropology within Quaternary science can be illustrated by some selected texts. In 1958,

Frederick Zeuner published the fourth edition of his highly influential synthesis, *Dating the Past: An Introduction to Geochronology* (Zeuner, 1958). A year later, he followed it with *The Pleistocene Period: Its Climate, Chronology and Faunal Successions* (Zeuner, 1959). The two volumes provide a benchmark with which to assess the current work of paleoanthropologists.

Zeuner's syntheses were dominated by the Pleistocene sequences of Europe that had been established in southern Germany 50 years before by Penck and Brückner. In 1959, research had barely begun in Africa, Asia, and Australia, and

the number of reliable sequences was very small. America did not possess a deep Pleistocene record for hominins although the glacial sequences had been established.

Zeuner's discussion of the archaeology was dominated by European typology and taxonomy, particularly in *Dating the Past*. Europe also loomed large in his discussion of the fossil record. There are, for example, very few references to the Australopithecines in either book even though they had been named 30 years before in South Africa. The state of play in 1959 is summarized in Table 2.

However, 1959 was a significant year for paleoanthropology outside of Europe. During their annual field season at Olduvai Gorge, Tanzania, Mary and Louis Leakey discovered a robust Australopithecine (*Paranthropus (Zinjanthropus) boisei*) in their excavations. The development of potassium/argon dating techniques and their application soon after (Leakey et al., 1961) to the volcanic tuffs that segment the long Olduvai sequence achieved a breakthrough that the Europeans could not match. The hominin 'living floor,' as Leakey (1971) referred to it, and where first *Zinjanthropus* and later *Homo habilis* (Leakey et al., 1964) had been found, was now dated in Bed I

Table 1 Three important terms in paleoanthropology. Hominin replaced hominid in the 1990s when the genetic classification of extant apes and humans caused a rethink of their ancestral relations. The use of the term, however, is not yet ubiquitous

Human	All living people and their recent Pleistocene ancestors
Hominin	The above, and all the Pliocene and Pleistocene fossil ancestors (genera and species) of humans
Hominid	The above, and the African great apes: chimpanzee, bonobo, and gorilla, and their fossil ancestors.

Figure 1 The interdisciplinary relationships involved in paleoanthropology. Foley (nd) with permission. Prepared for the NERC, Environmental Factors and Chronology in Human Evolution and Dispersal programme 2003.

Table 2 The Pleistocene framework for the study of hominins in 1959 (Zeuner 1959: 219). Zeuner was following the four Ice Age model of Penck and Brückner. The table reveals the paucity of fossil finds, mostly from Europe, and the classification of what there was into a very few species. The age estimates were based on a number of sources including the astronomical theory of the Serbian astrophysicist Milutin Milankovitch who died in 1958

Upper Pleistocene	Back to about 180 ka BP	Last glaciation (1) and last interglacial	<i>Homo sapiens</i> <i>Homo neanderthalensis</i>
middle Pleistocene	About 180 to 425 ka BP	Penultimate glaciation (2) and penultimate interglacial	<i>Homo cf. sapiens</i>
Lower Pleistocene	About 425 to 600 ka BP	Antepenultimate glaciation (3), antepenultimate interglacial, and early glaciation (4)	<i>Homo (Pithecanthropus) erectus</i> and <i>pekinensis Homo heidelbergensis</i>

BP = Before Present.

to more than 1.7 Myr old, placing the finds in the Pliocene. Moreover, the association of the fossil hominins with rich faunal remains and stone tools provided an opportunity to conduct a paleoanthropological investigation into the capabilities and adaptive behavior of these remote ancestors. Discussions of these data then ranged around the existence of central place foraging (Isaac, 1978), the contribution of hunting and scavenging to the diet (Binford, 1981; Bunn, 1981), and the importance of using modern analogs to distinguish hominin behavior from that of other accumulators and modifiers of bone and stone such as hyenas and rivers (Behrensmeyer and Hill, 1980; Brain, 1981).

Following this lead similar issues were tackled in Europe. The adaptations of hominins to their environment were studied by means of their stone technology as well as by using evolutionary ecology to analyze the decisions they had taken about where to stay and which parts of the landscape they repeatedly visited. A pioneering project in this emerging paleoanthropology took place in the Ambrona valley, Spain, led by Clark Howell and Emiliano Aguirre. While issues of dating and comparative stone tool typology were uppermost at their excavations of the Lower Paleolithic sites of Torralba and Ambrona (Howell, 1966), their aim was also to turn those bones and stones into information about the process of human evolution. As at Olduvai, the questions dealt with adaptations to the food quest: how did they get their food, what did they eat, and also did they eat well?

The excavations impressed because of their scale (Santonja, 2005) and the association of stone tools with elephant bones. Clark Howell, in his popular book *Early Man* (Howell, 1965), presented this association as evidence for big-game hunting by *Homo erectus* using Acheulean handaxes. The conclusions emphasized their human capacity to plan, cooperate, share, and instruct.

These capacities were summarized by Butzer (1982) who used his geological work to reconstruct the wider landscape to which the hominins were adapting. In his study, the two sites, Torralba and Ambrona, formed a hub in a network of movements that radiated over large distances as hominins adjusted to seasonal fluctuations in their food supply (Figure 2). Hominins would come together to hunt when game was migrating and then disperse in small groups across a much larger territory. An important factor in these seasonal movements was the high elevation (over 1000 m) for the sites suggesting that winters were harsh and that prey species would migrate in search of food. The ability to kill big game and to adjust population to the seasons all indicated modern capabilities for these handaxe makers.

Subsequently, several of these claims have been disputed and revised (Villa, et al., 2005), and the debate about the ability of early hominins either to hunt or to scavenge has seesawed with new and more precise evidence (Dominguez-Rodrigo, 2002; Stiner, 1994). However, whatever the outcome, and currently the hunting hypothesis commands the majority view (Gamble, 1999), these debates illustrate the questions that paleoanthropologists came to ask about Quaternary hominins. At the heart of these questions is the time depth of human rather than hominin behavior in the Quaternary and it is to these issues that the author will devote the rest of this contribution.

Adaptive Radiations and Climate Forcing

While paleoanthropologists work within the framework of evolutionary science, their approach, it has been claimed (Foley (2001), p. 5), is largely untouched by advances in evolutionary theory. New data and new methods in the last 50 years, and in particular the ongoing development of absolute chronologies, has led to the development of more complicated models of hominin ancestry. For example, one of the most significant findings in Bed I at Olduvai Gorge was the presence of two contemporary hominin genera, *Paranthropus* and *Homo*. The wealth of fossil hominins that have since been discovered in the Hadar region of Ethiopia, Koobi Fora in Kenya, and throughout the African Rift Valley, as well as the limestone caves of South Africa (Klein, 1999; Stringer and Andrews, 2005), have confirmed this pattern. At any one moment, there were several species present at a subcontinental scale and often within the same local geographical region. This is well illustrated at Koobi Fora where an African example of *H. erectus* was found in the same geological horizon, dated to 1.3 Ma, as a robust *Australopithecus* (Leakey and Walker, 1976).

These finds changed the basic model of hominin evolution. No longer was there a single species evolving in well-recognized anatomical stages toward modern humans. Instead, at any one time, there were several contenders, like branches on a bush, and the task of the paleoanthropologist was to decide, after a review of all the evidence, which one was indeed the ancestor.

The problem of deciding the path of human ancestry is illustrated by stone tools. For example, which of the two hominin genera at Koobi Fora (see above) had made the stone tools that were excavated from the same geological deposits? Furthermore, the observations of tool making and usage by chimpanzees at Gombe in the 1960s has now been extended to New World monkeys who use stones to dig for roots in Brazil. Such widespread technological competence has demanded a rewrite of the earlier certainties about technology and the evolution of the human brain. This is an ongoing debate currently concerned with the competence of the small-brained hominin *Homo floresiensis* from Indonesia to make the stone tools that have been excavated from Late Glacial levels in the Liang Bua cave (Morwood et al. 2004).

In order to inject a more theoretical perspective into paleoanthropology, Robert Foley (2002, figure 3) has recently proposed seven adaptive radiations in hominid evolution (Table 3; Figure 3). This model not only responds to the empirical evidence of many hominin species but also establishes a behavioral basis to the pattern of change that is evident in both the archaeology and anatomy.

Adaptive radiations, according to Foley, are based on the process of diversification that stems from dispersal, and the adaptive basis of these dispersals, rather than on the process of speciation. In his framework, dispersal is the mark of evolutionary success. It is an indication that speciation has occurred due to a combination of three factors: allopatry (or geographical isolation), local adaptation, and genetic drift.

The six hominin adaptive radiations are each characterized by a large number of species, and we can predict that an even larger number await discovery. The route to modern humans will not therefore be traced in a simple lineal fashion from one fossil species to another. Rather it will be through major

Figure 2 A reconstruction of the movements of Acheulean hunters on the Spanish meseta (after Butzer (1982)). (a) Intercept hunting during the spring and autumn game migrations. (b) The Ambrona valley used as a game trap. (c) Seasonal movement between camps of varying size provides a model of the archaeological evidence.

Table 3 Seven hominid adaptive radiations. The timescale is approximate

Suggested timescale	Adaptive radiation	Adaptive pattern	Grade	Representative taxa
Last 100 ka	7	Aquatic resources	Anatomically modern humans	<i>H. sapiens</i>
500 ka	6	Projectiles ?Fire	Larger-brained <i>Homo</i>	<i>H. neanderthalensis</i> <i>H. heidelbergensis</i>
1 Ma	5	Carnivory	<i>Homo</i>	<i>H. ergaster</i>
2 Ma	4		Earliest <i>Homo</i>	<i>H. rudolfensis</i>
3 Ma	3	Megadonty	<i>Paranthropus</i>	<i>P. boisei</i>
4 Ma	2	Bipedalism	<i>Australopithecus</i>	<i>A. afarensis</i>
5 Ma	1	African apes		

After Foley, R. A. (2002) Adaptive radiations and dispersals in hominin evolutionary ecology. *Evolutionary Anthropology* 11, 32–37.

adaptive changes that involved a suite of regional hominin forms that shared the major adaptive response of that radiation, such as carnivory or a composite weapon technology. The task of the paleoanthropologist, as reviewed by Potts (1998), is therefore to examine the evidence for significant territorial

expansion and longer, sustained occupancy in habitats that experienced variable climatic selection.

One example is the turnover pulse model (Vrba, 1996) that draws an explicit link between the timing of speciation among a range of African mammals, including hominins in the

Figure 3 The adaptive radiations of the hominins (after Foley (2002), figure 3). The radiations are described in Table 3. Key – *Ardipithecus*: RAM = *ramidus*. *Australopithecus*: ANA = *anamensis*; AFA = *afarensis*; AFR = *africanus*; BAH = *bahrelghazali*; AET = *aethiopicus*; GAR = *garhi*. *Paranthropus*: ROB = *robustus*; BOI = *boisei*. *Homo*: RUD = *rudolfensis*; HAB = *habilis*; ERG = *ergaster*; ERE = *erectus*; ANT = *antecessor*; HEI = *heidelbergensis*; HEL = *helmei*; NEA = *neanderthalensis*; SAP = *sapiens*.

Plio-Pleistocene, and the possible forcing effect of climate change (deMenocal, 2003). In particular, attention has been drawn to an explosion of new species between 2 and 2.4 Ma that is interpreted by Vrba as the impact of climate change on low-latitude forests and the opening up of new savannah habitats. This change would have favored a radiation of bovid species as wet and dry conditions alternated more rapidly. In Vrba's view, such turnovers are associated with ecological generalists who can adjust their feeding strategies to changing conditions in the environment. Once established, the possibility emerges for a rapid, pulse-like radiation into new niches, so producing a wealth of new taxa. Therefore, as soon as the environment has become 'saturated,' specialist adaptations with a different set of ecological strategies emerge (Gamble, 1993, pp. 87–89).

The argument is persuasive but a statistical examination (Foley, 1994) has shown that species appearance is not causally linked to climatic change as indicated in the marine cores. However, the same statistical study does show that species extinction is more likely to be climatically controlled (Foley (1994), p. 285). Foley's observation is important in establishing the nature of the link between climate change and hominin evolution on the large scale. The implication is that habitats where specialist feeders might normally be found are lost more quickly than they are gained. And if climate change during the Quaternary controls extinction, then we can see that a major biogeographical pattern in hominin evolution has been the repeated contraction and expansion of their geographical ranges. As Dennell (2003, p. 421) has pointed out, the question of 'how successful' these dispersals might have been has received far less attention than the 'when' and 'how often.' It is expected that within radiations 4–6 (Table 3), these contractions were frequent and short lived, especially in the northern areas of the Old World where climate exerted a more controlling effect through the seasonal distribution of food resources.

From Dispersals to Diasporas and the Legacy of the Pleistocene

The first six adaptive radiations (Table 3) all took place within the confines of the Old World (Table 4). Moreover, radiations 2–6, characterized by bipedalism, megadonty (large teeth), carnivory, and projectiles only achieved a restricted distribution within the Old World. For example, Siberia was not settled until the end of the Upper Pleistocene. This pattern helps to explain the late colonization of the Americas. Furthermore, even though stepping-stone islands existed to facilitate dispersal to a large, low-latitude island such as Madagascar, this did not occur during the Pleistocene. It was only adaptive radiation 7, marked by the use of aquatic resources, that saw a global distribution of hominins – a process, as the Australian and American evidence shows, that started no earlier than 60 ka BP and probably more recently in all the three continents.

The legacy of the Quaternary viewed from a hominin perspective is therefore a single species globally distributed (Table 4). The process by which the Old World and subsequently the globe came to be occupied by hominins and humans is now described as a series of first dispersals (Gamble, 1993) and then in adaptive radiation 7, diasporas (LL Cavalli-Sforza and F Cavalli-Sforza, 1995). The length of time it took to colonize the Earth and so realize the Quaternary legacy has been put down to cognitive limitations, a lack of transport technology (especially boats), and environmental barriers (particularly oceans) (Gamble (1993), chapters 2 and 3).

Three examples question these views.

1. The earlier dispersals of 2 Ma BP are characterized as multiple and frequent. Africa is regarded as the source and Asia/Europe as the recipient of population. However, this view has been questioned for the earliest dispersals. Robin

Table 4 Aspects of the two adaptive radiations of *Homo*

Adaptive radiations	1–6	7
Global habitats occupied	25%	100%
Duration	2–2.5 Ma	300–100 ka
Biological diversity	Multiple species, genera	Geographical populations, races
Technological skills	Generic and transferable	Place specific
Social networks	Local	Continental
Release from social proximity	Limited	Achieved
Climate change response	Retreat to refuge	Track from refuge
Representative taxa in <i>Homo</i>	<i>erectus/ergaster/heidelbergensis/helmei/neanderthalensis</i>	<i>sapiens</i>

After Gamble, C. S., Davies, W., Pettitt, P., and Richards, M. (2004). Climate change and evolving human diversity in Europe during the last glacial. *Philosophical Transactions of the Royal Society Biological Sciences* 359, 243–254.

Dennell (Dennell and Roebroeks, 2005) has pointed to evidence from Asia which suggests that one of paleoanthropology's most basic paradigms – dispersal by early *Homo* Out of Africa – needs rethinking. The Sahara was not the barrier to movement as often presented so that an earlier hominid dispersal could have resulted in the origin of hominins, and in particular the genus *Homo*, outside Africa with subsequent dispersal back 'into' that continent. This scenario is by no means proven but serves as an alternative hypothesis to the Out of Africa 1 model for the origin of the genus *Homo*. Consequently, Dennell and Roebroeks (2005, p. 1101) argue that what paleoanthropologists need are spatial units other than modern political boundaries in order to investigate such dispersals and their internal movements. They propose 'Savannahstan' as one such unit to model adaptations and dispersals since it links the Pliocene grasslands from west Africa to northern China.

2. The multiple dispersals of hominins is therefore a parallel to the multiple species that are now expected, apart from the present day, at any one time in the fossil record. The implications of such a pattern have been discussed by Marta Lahr and Robert Foley (Foley and Lahr, 1997) in the context of the origins of modern humans. Rather than a single diaspora of *H. sapiens*, the Out of Africa 2 model, they argue for repeated dispersals after 300 ka BP and that these included the much later diasporas into Australia and the Americas. The multiple dispersal model combines genetic, anatomical, and archaeological data.
3. The diasporas of the last 60 ka can be studied in greater detail as a result of enhanced preservation, greater chronological precision, and the use of molecular genetics to produce phylogeographies. The articles in this Encyclopedia on Australia and the Americas indicate the fine-grained control that is possible while a combination of genetic, archaeological, and radiocarbon evidence is allowing cross-checking on issues of timing and direction in the recolonization of formerly glaciated and periglacial areas of northern Europe (Gamble et al., 2004; Straus et al., 1996). Comparison of the radiocarbon dating of these Late Glacial diaspora and settlement patterns with the GRIP ice-core chronology of Greenland (Figure 4) reveals that another of paleoanthropology's basic paradigms – that climate warming encourages recolonization – is not supported, since populations left the southern glacial refuges in GS-2a, a time of extreme

cold. Following a rise in population numbers during GI-1 (Bocquet-Appel and Demars, 2000), the return to cold conditions in GS-1, also known as the Younger Dryas, did lead to a reduction in settlement numbers confirming, as we saw above, that Quaternary climates controlled extinction (population loss) rather than speciation (population gain) (Gamble et al., 2004).

Social Rather than Environmental Change

The move from dispersals to diaspora is a further example of the continuing debate among paleoanthropologists of where to draw the hominin to human line. Cognitive, technological, and environmental reasons do not seem sufficient to account for the limited Old World distribution of all hominins prior to the late diasporas of modern humans. The novelty of these later diasporas, as opposed to the earlier dispersals, was the release from social proximity which they achieved. This release characterizes a human as compared to a primate community (Rodseth et al., 1991). In other words, human social life was extended to include participants who were not always living together and who might be physically absent from their immediate social networks for lengthy periods (Gamble, 1999). This pattern of social extension is a hallmark of humans that does not appear to have been shared in such a dramatic way with other hominins. The evidence that their social lives were local (Table 4) comes from the limited distances that raw materials were transported (Féblot-Augustins, 1997). These were usually less than 5 km and rarely more than 80 km from source (Gamble (1999), Table 3.4). By comparison, diasporic humans exchanged shells and stone sometimes over distances of 1000 km and regularly over 100 km. This extension in the transfer and exchange of raw materials is supported by the ocean crossing to Australia and the rapid peopling of its hyperarid Pleistocene interior (Smith, 2005), that involved very low population densities and physical separation. But such colonization did not lead to a breakdown in social life as must have been the case when earlier hominins faced such socially challenging environments. With the final, aquatic (7) radiation, the emphasis now shifted to the construction of society over longer timescales and distances. This release from proximity was achieved by connecting people and places in an extended social network.

Figure 4 The pattern of recolonization of northern Europe from a southern refuge during the Last Glacial Maximum. The frequency curves show the distribution of radiocarbon dates and their increase points to the timing of population dispersal (after Gamble et al. (2004), figure 2). The radiocarbon determinations are calibrated using CALPAL (Weninger and Jöris, 2000) and presented by three major regions. Five population events associated with the dispersal are indicated. The distribution of radiocarbon dates points to the major dispersal, population event 3, preceding the warming of the Greenland interstadial. *N* = number of calibrated radiocarbon determinations in the frequency curve. Stratotype boundaries in GRIP ice-core years are as follows: GI-2 = 21.8–21.2; GS-2 = 21.2–14.7; GI-1 = 14.7–12.7; GS-1 = 12.7–11.5 ka BP.

Technological Modes and the Evolution of a Social Brain

Stone tools have been the main source for studying the significance of encephalization in hominin evolution (Schick and Toth, 1993; Wynn, 1993). Changes in Paleolithic traditions (Table 5) were once seen as a demonstration of progressive evolution. Each stage in the Lower–Middle–Upper (Zeuner, 1958) sequences was linked to a fossil hominin. However, as we have seen above, such simple correlations (Table 2) are no longer possible and the criteria which define such classification as the African Earlier–Middle–Later Stone Age are not as hard and fast as once thought. For example, the advent of radiometric

dating and the investigation of long stratified sequences, as at Klasies River Mouth, South Africa (Klein, 1999), have shown that stone blades, once considered a diagnostic type fossil of the European Upper Paleolithic and the African Later Stone Age, have a much greater ancestry. Blades are any intentionally struck stone blank that is at least twice as long as it wide. With such a definition, it is not surprising that blades frequently appear as elements in Middle Paleolithic and Middle Stone Age assemblages and the age of their appearance has been extended from some 40 ka BP to over 300 ka BP (Bar-Yosef and Kuhn, 1999).

An alternative scheme, proposed by Clark (1969), recognized five technological modes (Table 5). His approach has been widely followed as studies of Quaternary hominins and

Table 5 Technological modes in the Paleolithic

	<i>Dominant lithic technologies</i>	<i>Conventional divisions in Europe</i>	<i>Conventional divisions in Africa</i>
Mode 5	Micro lithic components of composite artifacts	Mesolithic	Later Stone Age
Mode 4	Punch-struck blades with steep retouch	Upper Paleolithic	
Mode 3	Flake tools from prepared cores	Middle Paleolithic	Middle Stone Age
Mode 2	Bifacially flaked handaxes	Lower Paleolithic	Earlier Stone Age
Mode 1	Chopper tools and flakes		

Clark offered the modes as a homotaxial sequence which at least in Africa and, at the time he was writing, in Eurasia followed the progression from mode 1 to mode 5. However, although he was writing a world prehistory, Clark never claimed his modes were universal stages (1969, p. 30). Instead, they were his attempt to escape from the historical thorn bushes of what to call prehistoric hunters and gatherers in different continents. For example, they certainly were neither Paleolithic nor Stone Age in Australia or the Americas. Reproduced from Clark JGD (1969) *World Prehistory a New Outline*, 2nd edn., p. 31. Cambridge: Cambridge University Press.

their technology became a truly worldwide endeavour and where the European Paleolithic and African Stone Age terms appeared anachronistic. However, one problem with Clark's modes is that they unduly privilege stone tools, and all other aspects of technology and material culture are forgotten. These would include wooden spears, hearths, huts, art, and items of display, all of which have a varied and complex history.

Clark's five technological modes do however highlight two aspects of hominin technology during the Quaternary. First, it was very static, and second, it did not follow the ethnographic pattern found among today's hunters and gatherers, where the local environment exerts a selection pressure on the shape, form, and complexity of technology. For example, mode 2, typified by large bifaces such as Acheulean handaxes, is first found in east Africa at 1.5 Myr BP and persists for more than a million years (Klein, 1999). Moreover, these bifaces are found from the equator to the northern latitudes of Britain and in environments with very different plant and animal resources, shorter growing seasons, and a range of adaptive challenges. As a result, the technological skills of the early hominins can be characterized as generic (Table 4). They could be transferred to environments as different as the tropical savannahs and the northern grasslands. A very different picture is presented by mode 4 technologies that, after the 60 ka diaspora, compare well in their diversity and complexity with those of contemporary hunters and gatherers and where the skills are specific to local conditions and places. However, the picture is further complicated by the evidence from Australia where mode 3 continued to the present day. Technology does not therefore correlate with particular hominin fossils and their assumed levels of intelligence and problem solving. In addition, the role of environmental selection on innovation and adoption of new techniques is restricted.

Technology, especially the appearance of art and ornament, has been used as a guide to major cognitive and behavioral changes, including language and symbolic thought (Mithen, 1996). However, an examination of hominin encephalization (Figure 5) by Aiello and Dunbar (1993) revealed that the most significant increase in brain size occurred half a million years ago by which time hominin brains were more than twice the size, proportionately, than any of the earlier Australopithecines. Using a comparative sample of living primates, they also showed how early hominin brain sizes implied much larger social groupings. They calculated that group size had risen at this time to at least 120, whereas the largest among primates is

Figure 5 The implications of increases in brain size during 3.5 Ma of hominin evolution (after Dunbar (2003)). At 500 ka, there is a marked encephalization. According to the social brain hypothesis, this resulted in an increase in group sizes and the amount of time that would have been needed daily to undertake physical grooming to maintain social ties. The 20% (lower solid line) of the day spent in social activities such as grooming represents a significant limit for today's great apes since they have to spend much of the day traveling and looking for food. This threshold would have been similar for the small-brained Australopithecines. The 30% of daily activity spent on grooming (dotted line) represents an upper limit beyond which other mechanisms of social integration such as language are needed. The primate-style social model was therefore exceeded at least 500 ka. AMH = anatomically modern human.

60. Dunbar (2003) has since expanded this observation into a social brain hypothesis: our social lives drove encephalization. In explanation, bigger brains have proportionately larger amounts of neocortex, the thinking part of the brain, that also manages relationships and interactions between group members. By 500 ka BP, hominin group size was now so much larger than those of primates that the traditional means of maintaining and organizing groups through physical grooming was no longer an option. Dunbar's suggestion is that language appeared at that time to facilitate interaction and organize larger social groupings. However, such an age is well before the fluorescence of art and ornament that appears in Europe some 40 ka. The social brain hypothesis focuses attention on how exactly technology, and material culture more generally, contributed to those tipping points in hominin evolution such as language.

The Human Revolution: Gradual or Abrupt?

My final theme, the human revolution, became one of the central concerns of paleoanthropologists in the 1980s (Mellars and Stringer, 1989). This was not the first time that the idea of a human revolution had been applied to the fossil and archaeological record. What marked this application out was the claim for recency. As Paul Mellars has shown (Mellars, 2005), the conjunction in Europe of innovation in technology and material culture coincides with the replacement of the native Neanderthals by incoming modern humans *H. sapiens* (Stringer and Gamble, 1993). The model of replacement was initially strongly contested by an ancient origin for modern humans, often described as multiregional evolution (Wolpoff, 1989). Its supporters argue that through a process of convergent evolution the founding populations of Out of Africa 1 in the late Pliocene evolved into the distinctive geographical populations, or races, that are encountered today. The model of a recent African origin for *H. sapiens* is also known as Out of Africa 2. The evidence now available from dating both the anatomical (McDougall et al., 2005) and genetic changes (Cann et al., 1987; Krings, 1997) indicates conclusively that modern humans originated in Africa.

The current interest in the human revolution model centers on its timing. The Upper Paleolithic revolution of Europe has been questioned by paleoanthropologists working in Africa (Wadley, 2001) and characterized as 'the revolution that wasn't' (McBrearty and Brooks, 2000). Excavations at Blombos Cave, South Africa, provide evidence that shell ornaments, engraved ochres, bone tools, and culturally specific projectile points were all present in excess of 80 ka BP (Henshilwood and Marean, 2003). Confirmation comes from Israel, based on the deliberate burial of modern people with items that can be interpreted as intentional grave goods more than 100 ka BP (Grün et al., 2005).

The issue that the human revolution therefore addresses is explaining why such a long delay occurred between the appearance of anatomically modern people in Africa and the suite of cultural changes that led eventually to the Australian and American diasporas. The African record is indeed more complex than once thought and of much greater antiquity. The claims (d'Errico et al., 1998) are also not convincing that Europe's Neanderthals produced their own independent cultural revolution that just happened to coincide with the arrival of modern humans from Africa (Mellars, 2005). As a result, attention has focused on the effect of major environmental events such as the eruption at 71 ka BP of Toba on Sumatra (Ambrose, 1998) and its impact through a prolonged volcanic winter on human populations that favored a subsequent African diaspora.

Revolution, with its accent on abrupt, dramatic change, is not an appropriate term at Quaternary timescales. Neither is the alternative tenable, namely, a gradual addition of innovation in culture and society. Much of the argument revolves around the identification of what constitutes art, symbolic behavior, language, and hence the modern mind (Mithen, 1996) among archaeological data. One person's evidence for art is another's scratched pebble (Marshack, 1972). These are difficult issues not helped by small samples, widely distributed through the Old World.

However, what is apparent is that the major African diaspora that led to modern humans peopling Australia, Europe, and later the Americas depended upon the social ability to extend society across time as well as space. This occurred with, as was the case in Europe, or without, as in America, either much art and ornament or mode 4 technologies, as the Australian record shows. Nobody disputes that these diasporas involved modern humans as defined genetically, anatomically, and socially. This cultural diversity suggests that paleoanthropology can no longer rely on universal processes to construct an understanding of the timing and sequence of changes among hominins. While the evidence from the paleoecological archives is vital to such discussions, the trend toward the detailed history of social and cultural development in selected regions is returning to favor (Straus and Bar-Yosef, 2001).

Future Prospects

These historical accounts will be assisted by a number of recent breakthroughs in Quaternary science, promising an equally productive and exciting next 50 years. Among many, three with the potential to transform the subject can be singled out:

1. adding to the continued precision of dating through such techniques as microtephras permitting independent, long-distance correlation that bring the study of contemporaneity down to below a single human generation within any single MIS;
2. tracing the phylogenies of fossils by analyzing their ancient DNA; and
3. using the direct, measures contained in stable isotopes to characterize hominin diet, and as a proxy for the provenance, and dispersal of hominins.

All of these, and many more techniques, will allow paleoanthropologists to use archaeological evidence in new ways. They will be able to analyze the material culture of our earliest ancestors as historical information in the unfolding story of human evolution during the Quaternary, and provide an examination of how deep-seated, or superficial, our current differences might be.

Introduction

The continent of Africa preserves the longest record of archaeological manifestations of hominin behavior beginning with the discoveries in the Kada Gona region of Ethiopia (Semaw et al., 1997). These artifacts, dating to 2.5 Ma, are Oldowan core and flake industries with associated hominin-modified bone. This overview focuses entirely on Africa during the long formative period of human prehistory known as the Early Stone Age (ESA, Oldowan and Acheulean Industries) spanning from about 2.5 Ma to 200–300 ka. All of the assemblages discussed in this section predate technological innovations such as point production, hafting, blade production, and core-reduction methods such as the Levallois technique. These later techniques characterize the Middle and Later Stone Age and will not be part of this review.

The ESA of Africa is divisible into the Oldowan Industry (Industrial Complex) or the Acheulean Industry (Industrial Complex). The Oldowan tradition of craftsmanship is characterized by simple fist-sized cores and whole flakes produced by hand-to-hand hard hammer percussion flaking, where the cobble or nodule from which flakes are to be removed is held in one hand and a dynamic blow is delivered with a stone hammer from the opposing hand. Instances of the bipolar technique, where the cobble is placed on a hard surface or anvil and a flake or detached piece is removed by initiating a wedging fracture with a hard hammer, also exist at some sites. Fixed design core forms are usually lacking and there is minimal secondary retouch on whole flakes. More formalized tools that appear in some industries appear to be the result of raw material shapes and the properties of these stones. Assemblages attributed to the Oldowan Industry *sensu stricto* range in age from 2.5 to 1.8/1.7 Ma. The Oldowan was first described by Mary Leakey from assemblages found at Olduvai Bed I (Leakey, 1971). These industries fall into the mode I technique described by Clark (1969). The transition to the beginnings of the Acheulean Industry dates to between 1.7 and 1.5 Myr and is marked by highly variable assemblages that contain examples of larger cores, larger flakes, rare instances of crude bifaces as well as the previous suite of artifacts usually associated with the Oldowan Industrial Complex. Industries in this time range have collectively been called the Developed Oldowan (see Figure 1).

While there is no total agreement on the actual definition of this term, technological studies of these assemblages have referred to these industries as early Acheulean (Ludwig and Harris, 1998).

The earliest well-documented and unequivocally Acheulean assemblages are found at Konso-Gardula (Ethiopia), FxJj 63 (Kenya), and EF-HR (Olduvai, Tanzania) dating to approximately 1.5 Ma. These assemblages are characterized by large bifacially flaked hand-axes and cleavers made on much larger flakes than is evident in the Oldowan. These flakes are struck

from heavier and larger cores. Smaller but nonetheless significant retouched flake tool forms constitute a conspicuous part of the Acheulean stone tool assemblages. Through the course of the Acheulean Industry, there appears to be a general trend toward thinner cores produced through techniques of bifacial thinning. Bifacial thinning is often conducted using a soft hammer, usually a wood or bone billet. These assemblages are often associated with the onset of the Levallois core technique of core preparation. Sites from the Acheulean industry are found in a much broader geographical range than the previous Developed Oldowan sites (see Figure 2). The Acheulean Industry is succeeded in the geological record by stone assemblages attributed to the Middle Stone Age (MSA) between 200 and 300 ka with the earliest MSA, dating to around 280 ka in the Kapthurin Formation, Kenya (Tryon and McBrearty, 2002). The Acheulean would fall into the mode II of the schema proposed by Clark (1969).

One of the most important events in human evolution was the dietary shift toward meat-eating that, for the first time, put our earliest stone tool-using ancestors in competition with large carnivores that remained dangerous predators. In previous ESA studies, some interpretations of hominin subsistence strategies have relied heavily upon the stratigraphic association of fragmentary animal bones and stone artifacts and overlooked the range of taphonomic processes that may have contributed to the accumulations of artifacts and bones excavated from archaeological sites. Archaeologists have since realized that agents other than hominins, including carnivores, disease, droughts, and water flow, may contribute to the formation of an archaeological site. As a result, identifying the relative contribution of hominins to the accumulation of archaeofaunas has become the focus of zooarchaeological investigations, requiring a theoretically grounded body of research directed at identifying the traces left by various taphonomic agencies (Binford, 1981). Bone-surface modifications including stone tool cut marks, hammerstone percussion marks, and carnivore tooth marks have proved to be the most reliable indicators of hominin and carnivore involvement in the accumulation of bone assemblages and since the first descriptions of cut marks by Bunn (1981) archaeologists are no longer dependent on the association of artifacts and bones to infer hominin involvement in site formation. Therefore, two types of bone assemblages will be discussed here, those that exhibit evidence of hominin-induced bone-surface modifications and those that do not.

Oldowan

The discovery of artifacts in the Kada Gona in sediments that are securely dated to 2.5 Myr sets the base of the archaeological record (Semaw et al., 1997). It is very likely that the earliest tool use has not been found in the record because sites are too

Figure 1 Site localities attributed to the Oldowan Industrial Complex on the African Continent. These include sites that have been collectively called Developed Oldowan and Oldowan.

diffuse or scattered (Panger et al., 2002). However, current archaeological data support the evidence of 2.6 Myr as the onset of technological evolution. Oldowan assemblages that represent the technological system of the earliest tool makers are confined to time periods between 2.6 and 1.5 Myr (see Figure 3).

The majority of these sites are confined to the eastern rift valley of Ethiopia, Kenya, and Tanzania, although sites can be found as far north as Algeria (Ain Hanech) and as far south as South Africa (Sterkfontein) (see Figure 1). Further fieldwork in northeast (e.g., Eritrea) and Northwest Africa (e.g., Morocco) could begin to fill in the current gaps in the geographical range of Oldowan industries. A notable exception to the Africa-centered distribution of Oldowan sites is the remarkable discovery of Oldowan-like artifacts in the Republic of Georgia at the site of Dmanisi (Gabunia et al., 2001). New research in eastern and central Asia suggests hominins began encroaching on these areas in the early Pleistocene.

The classic African Oldowan assemblages are found in sediments that are dated to between 2.6 and 1.8 Myr. The earliest sites are found in the lower Awash River Valley of Ethiopia at three major Oldowan research areas. The oldest of these three localities are found in the Gona region in drainages feeding into the modern Awash River (Semaw et al., 1997). These sites were located near large cobble conglomerates, likely on the

floodplains of a paleo-Awash river. These sites also preserve some of the earliest evidence of stone tool use in the form of cut marked bones at a few localities in the Dana Aouli and Ounda Gona drainage system (Dominguez-Rodrigo et al., 2005). Sites in the adjacent Hadar region also preserve numerous evidence of stone-flaking activity (Kimbel et al., 1996). Further south in the Middle Awash research area, evidence of stone tool use occurs only in the form of hominin-modified bone at the site of Bouri (de Heinzelin et al., 1999). The lack of stone artifacts at this site has been suggested to be the product of early hominin ‘curation’ of stone used for the manufacture of tools. Similar patterns of artifact transport have been suggested for sites in East Turkana where hominin-modified bones are found without associated tools (Harris et al., 2002).

The Turkana Basin in northern Kenya arguably contains the most productive deposits for studying the earliest archaeology. The oldest sites are found in the lower Omo valley in the Shungura Formation. The assemblages are dominated by quartz raw material and are often suggested to be the product of expedient bipolar reduction of pebbles. However, re-analysis suggests that a relatively high degree of planning went into the hard hammer percussion of small pebbles in some of these early Omo assemblages (de la Torre, 2004). This interpretation of the Omo assemblages is particularly interesting given the fact that sites of a similar age in the

Figure 2 Site localities attributed to the Acheulan Industrial Complex on the African Continent.

Nachukui Formation on the West Side of Lake Turkana show evidence of markedly variable skill levels in artifact production. The Lokalalei 2c site shows evidence of well-defined rules in stone tool production and core reduction (Delagnes and Roche, 2005). The appearance of stone artifacts is presently only known from the KBS Member (1.89–1.65 Myr) in the Koobi Fora Formation on the eastern shores of Lake Turkana (Isaac, 1997). These sites are dominated by freehand percussion of basaltic materials (Isaac, 1997). However, further north on the east side of Lake Turkana at the site of Fejej (de Lumley and Beyene, 2004), bipolar reduction of small quartz pebbles is the most common form of core reduction. This dichotomy in stone tool production is considered to be caused by the differences in available raw material in the different parts of the basin and attests to the limited mobility of the earliest tool makers (Rogers et al., 1994).

However, new evidence from the site of Kanjera South in western Kenya suggests the majority of the raw material used

for artifact manufacture was transported to this site (Plummer, 2004). It is quite likely that the technological system found at the Kanjera sites is unique among Oldowan localities. Transport and selection of specific raw materials seems to be a very tightly constrained part of the technological organization at Kanjera (Braun et al., 2005). Similarly, transport of materials at Olduvai Gorge seems to follow some specific patterns about the use and manufacture of tools. Recent landscape archaeology studies in the Olduvai basin have suggested that hominins practiced selective transport over long distances but movement of raw materials over shorter distances did not seem to abide by the usual relationship between distance from stone source and attrition of a specific raw material in an assemblage.

Although there is general agreement that Oldowan hominins could consistently flake stone, there is considerable disagreement over the relative skill level of the first toolmakers. Research at the Gona sites has suggested that even at the very inception of stone tool technology, Oldowan hominins had

Figure 3 Oldowan core, initially classified by M.D. Leakey (1971) as a chopper in her terminology.

already mastered stone fracture mechanics (Semaw et al., 1997). However, the evidence from West Turkana shows marked variation in the ability of early hominins to produce flakes and reduce cores in a systematic way (Delagnes and Roche, 2005).

Faunal assemblages associated with Oldowan artifact assemblages are dispersed throughout Africa with the earliest of these occurrences in East Africa. Hominin-induced modifications have only been identified from a few of the Oldowan artifact-bone concentrations that have been excavated. However, the absence of hominin-induced bone modifications is not always an indicator of the lack of hominin involvement in the formation of a bone assemblage. In fact, it may be the result of poor bone-surface preservation that obscures bone-surface modifications due to the simple fact that few bone assemblages have been subjected to analyses concerned with the identification of bone-surface modifications. Localities that have produced Oldowan bone assemblages that have been identified as archaeofaunas based on their spatial association with artifacts include Hadar, Middle Awash, Omo (Shungura Formation), and Melka Kunture in Ethiopia; Upper Semliki Valley in the Democratic Republic of Congo; Ain Hanech and El Kherba in Algeria; and Sterkfontein in South Africa (Plummer, 2004). Localities that have produced Oldowan bone assemblages that exhibit evidence of hominin-induced modifications include Gona and Bouri in Ethiopia; Kanjera South, West Turkana, and Koobi Fora in Kenya; and Olduvai Gorge in Tanzania. These sites have the potential to provide insights into the subsistence capabilities of hominins and the interactions between hominins and carnivores who were competing for animal carcasses.

Sites that preserve bone-surface modifications range in composition from a few cut-marked bones found on the surface to thousands of bones that preserve modifications induced by both hominins and carnivores. The earliest examples of cut-marked bones come from the finds at Gona and Bouri in Ethiopia and date between 2.5–2.6 Myr. These sites are important in that they represent the beginning of a dietary shift toward meat eating that coincides with the earliest evidence of stone tool manufacture. However, due to the extremely limited number of bones preserving hominin-induced modifications at these sites, it is difficult to determine the extent of hominin carnivory in this remote time period. As a result our

conception of early tool-using hominins as hunters or scavengers is still open to interpretation.

The majority of attention from studies interested in interpreting early hominin food acquisition has been focused on the bone assemblages excavated from the FLK 22 site, Olduvai Gorge, Tanzania and the co-occurrence of hominin- and carnivore-induced modifications that are associated with carcass consumption. Some authors assert that the abundance of cut marks on bones from Plio–Pleistocene archaeological sites indicates that hominins had primary access to flesh (Dominquez-Rodrigo, et al., 2002), whereas others argue that cut marks result only from the removal of scraps of flesh after large cats had primary access to carcasses (Blumenschine, 1995). While a consensus has still not been reached on the food acquisition and consumption practices of Oldowan hominins at FLK 22, archaeologists generally agree that by 1.8 Myr hominins were depending more on nutrients obtained from carcasses than their predecessors at 2.6 Myr. These findings have extensive implications for the behavior of *Homo erectus*, a species that appears in the fossil record at about this time. It is possible that a major reason for the success and geographic radiation of *H. erectus* is the incorporation of larger amounts of high-quality protein (meat) in the diet.

Transitional Industries: Developed Oldowan–Early Acheulean

Assemblages of artifacts and bones found between 1.7 and 1.5 Myr are often described as Developed Oldowan industries. Many of these sites appear to have a mixture of features associated with both mode I and mode II industries. These ‘transitional’ assemblages include the variability of the earliest Oldowan assemblages but are also precursors of the imposition of form on core morphology. This pattern is manifested in the repeated use of particular forms or core-reduction techniques. The clearest example of this appears in the Karari Industry on the east side of Lake Turkana (Harris and Isaac, 1976) with the introduction of larger ‘scraper’ forms that dominate the Oldowan assemblages after 1.6 Myr. Similar patterns can be found in sites such as Peninj, Chesowanja, and Gadeb (see Figure 4).

The appearance of these ‘transitional’ industries that are usually grouped with the Oldowan but show technological similarities with mode II industries suggests a continuity in the Paleolithic record which may argue against previously suggested models of episodic change in ‘cultural evolution’ (Semaw et al., 1997). These transitional industries are particularly interesting because at about 1.8 Myr (or possibly earlier), fossil remains attributed to *Homo ergaster* (or early African *H. erectus*) began to appear in sediments in East Africa. Well-preserved cranial and postcranial remains from Lake Turkana basin, most notably the Nariokotomie skeleton (KNM-ER 15 000), reflects major changes in the anatomy and physiology of hominins at this time. The concurrent change in the archaeological record represented by transitional (Developed Oldowan and Early Acheulean) assemblages may record a shift in behavioral complexity of this new hominin form (see Figure 5).

Behavioral traces from this time period began to be found in habitats that were not previously exploited by early

hominins, such as highland plateaus (Gadeb, Melka Kunture) and possibly drier savannah habitats, on the floor of the East African Rift Valley at sites such as Koobi Fora and Olduvai. Although it is difficult to make a strict link between these transitional assemblages and the appearance of *H. ergaster*, certain aspects of the biology of a larger hominin, such as

Figure 4 Developed Oldowan or Karari Industry core, initially classified as a Karari core scrapper; Harris and Isaac (1976).

secondary altriciality and larger home range sizes, suggest links between behavior and biology. These anatomical changes complement the archaeological record, which suggests increased efficiency in raw material procurement and use in these transitional industries. This is consistent with possibly complex foraging strategies, which may have been linked to an economic organization which included a highly variable tool-kit adapted to more variable ecological settings.

Acheulean

The Acheulean Industry is often described as mode II industry. **Figure 2** displays the localities of Acheulean sites distributed over large parts of the African continent. All of them include some of the characteristic hand-axes that mark the transition to mode II industry. Often referred to as large cutting tools, these larger implements are the hallmark of the Acheulean Industry (see **Figure 6**).

Acheulean sites are now known to exist in the African interior in particular, in more open, elevated, drier parts of sedimentary basins (e.g., Olduvai Bed III, Koobi Fora-Chari Member), and on the high plateaus of the flanks of the east African rift valley at high altitude (e.g., Gadeb, Isenya). Acheulean sites are found in a wide variety of settings including marine beach localities in northwest Africa (e.g., Sidi Abderrahman) and along the eastern and western coastlines of the southern part of the continent (Baia Foura and Amanzi). The distribution of sites does not necessarily indicate the penetration of the tropical rainforest in the watersheds and main drainages of the Congo River basin or the more forested regions of West Africa. However, the presence of Acheulean toolmakers is indicated in the more closed habitats of east Africa such as the site of Nsongezi, Uganda. Sites located

Figure 5 Important shifts in behavioral complexity of early African *Homo erectus* or *Homo ergaster* associated with Developed Oldowan and Early Acheulean archaeological assemblages. (Modified after Rogers, Harris, and Fiebel, 1994)

Figure 6 Acheulean biface or handaxe, which may have had multiple uses, including as a core for the production of flakes.

in this setting commonly have thick and broadly flaked bifaces, often attributed to the Sangoan tradition. Acheulean sites are also found in and around the margins of the Sahara desert. During the Pleistocene, these more arid regions may have undergone dramatic oscillations, which would have been host to less harsh steppe environments (Isaac, 1982).

In addition to the diversity of topographic and ecological settings, Acheulean sites are known from open air and cave settings. In most instances, Acheulean sites are characteristically found near water sources (spring deposits or fluvial systems). Overall, the presence of these sites in these varied habitats suggests that *H. ergaster* and subsequently *H. heidelbergensis* exploited a diversity of habitats. It can be inferred that the increased dietary requirements of these more encephalized hominins forced increased home and day ranges, which led to an ever-increasing overall geographic range resulting in a pan-African distribution. The perils of exploiting open habitats would have been ameliorated by the larger body size of *H. erectus* as well as the possible use of fire. The behavioral package displayed by *H. erectus* (and later *H. heidelbergensis*) would have allowed this hominin to survive in a niche that would have required direct competition with the Pleistocene carnivore guild. Controversial evidence for the control of fire exists as early as 1.5 Myr at Koobi Fora, Chesowanja, and Gadeb. It has yet to be proved whether fire was an adaptive tool to enhance access to high-quality food items in more open grasslands as well as high-altitude settings subject to freezing overnight temperatures. Yet by 300–400 ka, evidence at Kalambo Falls of charred logs, ash, and fire-reddened soil indicates unequivocal use of fire by hominins by the middle Pleistocene (Clark and Harris, 1985). Furthermore, ash deposits at the Acheulean sites of Cave of Hearths and Montagu Cave in southern Africa indicate that this was definitely part of

middle Pleistocene hominin adaptations. The substantial changes in the body size of middle Pleistocene hominins and concurrent encephalization would have required a shift in diet that facilitated increased nutritional intake (Milton, 1987). The exploitation of larger mammal carcasses may have provided a source for this increased nutritional intake. Therefore, assessing changes in the subsistence capabilities between *H. ergaster* and their Oldowan hominin ancestors is essential to determining the significance of meat eating in Plio–Pleistocene hominin evolution. Despite the obvious importance of Acheulean archaeofaunas, very few of these assemblages have enjoyed the full suite of taphonomic analyses. Acheulean sites that have produced extensive faunal assemblages include Ternifine, Sidi Abderrahman, and Bir Tarfawi in north Africa; Bodo, Melka Kunture, Gadeb, Karari (Koobi Fora), Konso, Kapthurin, Kanjera North, Kariandusi, Kilombe, Olorgesailie, Isenya, Lainyamok, Olduvai (Bed III–IV), Ndutu, and Peninj in east Africa; and Kalambo Falls, Wonderwerk, Swartkrans, Sterkfontein, Amanzi, and Elandsfontein in southern Africa. Despite an abundance of sites, meaningful interpretations of Acheulean hominin behavior are limited because several of these sites are from secondary contexts. Winnowed or transported assemblages often do not have the integrity required to make meaningful behavioral interpretations. Subsequently, many of these assemblages are overlooked in discussions of Acheulean paleoenvironmental context or the dietary adaptations of Acheulean hominins. Recent zooarchaeological investigations of Acheulean assemblages are beginning to produce interesting results. New rounds of data analysis, including sites such as Swartkrans (South Africa) and Peninj (Tanzania), are intermediary sites that are associated with ‘Developed Oldowan’ and Acheulean lithic assemblages. The association between the faunal remains and lithic assemblages at Swartkrans is still tenuous. Yet, the faunal assemblages at Peninj in Tanzania demonstrate clear differences between the ecological contexts of accumulations associated with Oldowan tools and those associated with Acheulean bifaces (Dominguez-Rodrigo et al., 2001). At Peninj, Oldowan-like tools are found near the basin margin and are associated with butchery activities. In contrast, the riverine deposits further from the Natron basin axis are found in fluvial contexts and are devoid of archaeofaunal evidence. Phytolith analysis of Acheulean hand-axes at Peninj suggests these bifaces were being used as wood-working tools. The subsequent inference is that the behavioral repertoire represented at these sites also included wooden spears, which subsequently eroded away. At all the sites found in Peninj, hominins are believed to have acquired early access to carcasses based on the anatomical location of cut marks on long bone fragments (Domingo-Rodriguez et al., 2002). This may indicate that Acheulean hominins were hunting or confrontationally scavenging to obtain meat, rather than passively scavenging flesh scraps and marrow from carnivore kills as their Oldowan hominin ancestors are believed to have done.

Excavations at other Acheulean sites, including Olorgesailie and Olduvai Gorge, have recovered Acheulean bifaces in association with extensive faunal remains (Leakey and Roe, 1994; Potts et al., 1999). Olorgesailie preserves an association between the bones of 57 giant gelada baboons and over 4000 stone artifacts, which, along with breakage patterns, lead some researchers to infer that hominins, were hunting baboons

(Shipman et al., 1981). Taphonomic analyses of this assemblage and other assemblages are in progress and will presumably reveal the diversity of hominin dietary adaptations during the middle Pleistocene. Of particular interest is whether the behavioral patterns seen at Peninj are a local response to the ecological contexts of the Natron basin or are indicative of an overall Acheulean pattern. The Middle Awash Valley of Ethiopia has preserved an extensive record of the Acheulean, dating between 1.0 Ma and 0.1 Myr (Clark and Schick, 2000). The artifact-bone concentrations are found in both primary and secondary contexts with several localities preserving bifaces in association with hominin-modified bone. The Herto Member (400–100 ka) hippo butchery sites in the Bouri Formation hold special interest in this regard. Here, bifaces are found in association with several hippo butchery sites; they exhibit evidence of hominin-induced modification to bone including a hippo cranium with large chop marks, suggesting bifaces may have been used to butcher large animal carcasses.

The incorporation of plant foods into the diet of *H. erectus* cannot be underestimated, even though plant remains are sparse in the archaeological record. Edible plant foods such as fruits, nuts, berries, roots, tubers, and seeds may have been important ‘fall-back foods’ in times of environmental stress. Two Acheulean sites, Amanzi Springs and Kalambo Falls, in southern Africa have evidence of preserved plant materials due to the waterlogged conditions of the sediments. At both sites, woods and seeds are preserved. At Kalambo Falls, evidence of fruit underscores the potential of these food items. These discoveries at Acheulean sites underscore the importance of plant foods in the overall diet of *H. erectus*.

The presence of bone tools in early Pleistocene archaeological sites in South Africa and East Africa contributes to our understanding of the diversity of tools incorporated into early hominin’s foraging practices. A recent study of the collection of bone tools from Member 1–3 (1.8–1.0 Myr) at Swartkrans (South Africa) shows that, in some instances, there was an intentional grinding to modify the polished pointed surface of bone tools. It is believed that this practice increased the digging efficiency of these tools, particularly in opening termite mounds (Backwell and D’Errico, 2005). The clear time investment in tool manufacture for termite extraction emphasizes the importance of insect foods as a source of protein in the Acheulean diet. The bone tools from Olduvai Gorge in East Africa (Leakey and Roe, 1994) were deliberately flaked into mostly irregular shapes. Some of the more heavy-duty hammer and anvil tools may have been used in large mammal carcass-processing (Backwell and D’Errico, 2005). The geographical differences may be a reflection of regional adaptations to foraging for variable food resources. This would be taken to reflect the flexibility of *H. erectus* to exploit a great diversity of food resources that might have been only seasonally available in different ecological settings. One interpretation of the variation in bone tool production strategies is that different hominin taxa (*Paranthropus robustus* in South Africa and *Australopithecus boisei* in East Africa) created these different industries.

Highly variable assemblages including more advanced core preparation and flake removal techniques attributed to the Levallois technique also characterize the final stages of the Acheulean. In addition, numerous middle Pleistocene assemblages are associated with more elongated thick core axes,

pick-like bifaces and a variety of small retouched or utilized flakes generally designated as Sangoan. The Sangoan tool assemblages could be viewed as a transitional industry as they continue the tradition of bifacial core axes and pointed forms. These industries could represent early manifestations that are present in younger industries that characterize the MSA.

Conclusion

A major unresolved issue in the ESA is whether the beginnings of Oldowan tool manufacture and use occurs abruptly in a punctuated period of cultural evolution or the origin of tool use has been a gradual event. An alternative hypothesis would be that stone tools were part of a behavioral repertoire of earlier Pliocene hominins that have yet to be recovered in the archaeological record. Based upon the current evidence in the Kada Gona region, the beginnings of stone tool manufacture could be interpreted as an important adaptive threshold or innovation occurring abruptly, perhaps in response to changing environmental conditions brought about by a major global cooling event between 2.8 and 2.4 Myr. This time interval also coincides with an adaptive radiation of the Homininae. It is possible that a more efficient processing of sources of high-quality protein facilitated this adaptive radiation. The incorporation of high-quality protein (presumably meat and marrow) and other nutritious food sources into the diet of one hominin species (most likely early *Homo* or by multiple hominins including the australopithecines and paranthropines) surely changed regional ecological dynamics in the early Pleistocene.

Clearly by 1.5 Myr (if not earlier), there does seem to be a correspondence between anatomical change and technological elaboration characterizing the Developed Oldowan and early Acheulean toolkits. The increasingly widespread nature, geographically and ecologically, of Acheulean sites may be linked to the emergence of a bigger-bodied hominin (early African *H. erectus* or *H. ergaster*). Through the course of the time period associated with Acheulean assemblages, large bifacially flaked cutting tools appear to become more refined and the end of the Acheulean is associated with prepared core technologies.

The growing complexity of the toolkit and evidence of a wide-ranging hominid inhabiting more diverse locations on the landscape may indicate the increasing intelligence, mental mapping, and growing social complexity in Acheulean lifeways. A possible indication of interpersonal group conflict comes from cut marks found on the human cranium recovered at the site of Bodo, in the Middle Awash region of Ethiopia. This specimen, attributed to *H. heidelbergensis* is associated with a large occurrence of Acheulean tools. The extent of the hominin modification found on this specimen suggests it was intentionally defleshed. This rare Bodo example may be one of the earliest recorded instances of cannibalism. This evidence may indicate that symbolic behavior, more characteristic of anatomically modern humans and their associated MSA technologies, had its beginnings in the late Acheulean. It is possible that many of the features Paleolithic archaeologists often associate with the development of modern human behavior had their roots in the deep time of the ESA.

2.7 Myr–300 000 Years Ago in Asia

R Dennell, University of Sheffield, Sheffield, UK

© 2013 Elsevier B.V. All rights reserved.

Introduction

In the early twenty-first century, we know as little about early human evolution and settlement in Asia as we knew about that of East Africa in the early 1960s (when *Homo habilis* and *Zinjanthropus* were first discovered), and compared to Europe and much of Africa, there is still a chronic shortage of well-dated sites >300 ka, especially those with associated faunal, fossil hominin, and environmental evidence. Consequently, most statements about Asia's earliest inhabitants are highly vulnerable to new discoveries. Relevant examples from recent years are the wholly unexpected discoveries of very primitive and small-brained hominins dating from 1.75 Ma in Dmanisi, Georgia, the diminutive late Pleistocene hominins from Flores, the Denisovans from Siberia, known only from their ancient DNA, and the re-dating of the earliest archaeological evidence from China to >1.5 Ma. Dennell (2009) provides a comprehensive summary of the Asian evidence before 125 ka. The first issue to consider is when hominins first inhabited Asia.

Early Pleistocene Hominins in Asia

The history of hominins in Asia before 300 ka is often summarized as the outcome of a dispersal event from Africa ca. 1.8 Ma, also known as "Out of Africa 1". However, very little is known about the faunal record of much of Asia before 1.7 Ma, and it remains unclear when hominins first left Africa. Because australopithecines were already in Chad, 2500 km west of the Rift Valley, 3.0–3.5 Ma, some may already have been in Southwest and other parts of Asia by this time. Hominins might also have left Africa shortly after the flaking of stone to make tools became routine ca. 2.6 Ma in East Africa (Dennell and Roebroeks, 2005). Indications of when hominins might have left Africa are provided by the sapropel record of the East Mediterranean (Kroon et al., 1998), and the loess/paleosol record of North China (Huayu Lu et al. (1999); see Figure 1). Sapropels are organic-rich sediments associated with greater inputs of fresh water into the sea; those in the East Mediterranean resulted largely from increased influx from the Nile, presumably during periods of higher rainfall. The Chinese loess and paleosol sequence indicates numerous alternating cool and dry glacial periods, and warmer and moister interglacial ones. Both records indicate several 'windows of opportunity' before 1.7 Ma, during which rainfall and temperatures, and hence biological productivity, were higher, and conditions more favorable for hominins to disperse. In intervening cooler and drier periods, deserts (particularly those between northeast Africa and Southwest Asia) would have encroached onto grasslands, and reduced opportunities for animals such as hominins to move freely between Africa and Asia (Dennell 2013).

At present, the earliest skeletal evidence for hominins in Asia dates from ca. 1.75 Ma from Dmanisi, Georgia and ca. 1.6 Ma from Java (see Figure 2 and Table 1).

Early Pleistocene Hominin Remains from Java and Dmanisi

The hominin remains from Java are classified as *H. erectus sensu stricto*, and were first discovered there in 1891, at Trinil. The earliest hominins from Sangiran date from ca. 1.6 Ma (Larick et al., 2001), and the child's cranium from Mojokerto, which had been dated to 1.81 ± 0.04 Ma, has now been re-dated to <1.49 Ma (Morwood et al., 2003). In The Dmanisi hominins have been precisely dated by paleomagnetism and Ar^{40} to ca. 1.75 Ma. They are remarkably small-brained and were probably 1.5 m or less in height, and their post-cranial skeleton exhibited an interesting mixture of modern and archaic features (Lieberman 2008). The Dmanisi hominins have proved difficult to classify. One mandible has been assigned to a new taxon, *H. georgicus*. The crania are very primitive, and show many resemblances to *H. habilis*. The most authoritative taxonomic assessment is that they are a very primitive form of *H. erectus sensu lato*, and may be ancestral to both early East African populations of *H. erectus* (or *H. ergaster*) as well as the Javan *H. erectus sensu stricto*. That is to say, *H. erectus* may have originated in Asia, and then migrated back into Africa, as well as eastwards across southern Asia to Java and possibly north China. Until more is known of the fossil record of Southwest Asia, this possibility cannot be excluded (Rightmire et al., 2006). The most significant aspect of the Dmanisi evidence is that hominins did not need large brains or bodies in order to venture out of Africa; this clearly implies that earlier, small-bodied and small-brained hominins might also have done the same. Some researchers have, for example, suggested that the late Pleistocene, diminutive *H. floresiensis* (the "hobbit") from Flores, Indonesia (see below), has australopithecine affinities, which may in turn imply a very early dispersal event by the hobbit's ancestors from Africa.

Early Pleistocene Lithic Technology in Asia

Examples of early Pleistocene lithic technology are now known from five regions of Asia. The main evidence for the earliest stone technology of early *H. erectus* in Asia comes from Dmanisi (de Lumley et al. (2005) in the Caucasus; see Figure 3). Here, the earliest tools predate the hominin remains and are ca. 1.85 Ma (Ferring et al., 2011). The artifacts are very simple (in keeping with the primitive nature of their makers), and have been called pre-Oldowan on technological grounds because of the absence of retouched tools. On-going research in Armenia indicates that bifacial Acheulean assemblages are older than 1.4 Ma and possibly ≥ 1.75 Ma (Presnaykov et al., 2012); if the

Figure 1 Climatic change and hominin dispersals: the oxygen isotope, East Mediterranean sapropel and Chinese loess records. As can be seen, there were numerous opportunities for hominins to disperse out of, into, and within Asia during the late Pliocene and early Pleistocene. Wilson et al. (2000), figure 4.15; Kroon et al. (1998), figure 3; and Hyayu Lu et al., (1999), figures 2 and 3.

older ages are confirmed, a major re-assessment will be needed of the origins of the Acheulean in Asia. The next oldest sites with stone tools are from the Nihewan Basin in North China, where the sites of such as Majuangou and Xiaochangliang are dated by paleomagnetism to ca. 1.66 and 1.36 Ma, respectively (Zhu et al. (2003, 2004); see Figure 4). These assemblages are broadly similar to Oldowan ones from East Africa that date from 2.6 Ma (see 2.7 Myr–300 000 Years Ago in Africa), and comprise flakes and the cores from which they were struck. The cores are simple in that they were not shaped prior to flaking, and no attempts were made to detach flakes of particular sizes or shapes. The main types recognized are choppers (cores with a few flakes struck from opposing angles), knives and scrapers (i.e., flakes with a sharp edge suitable for cutting or scraping).

The Levant also has an extremely long record of Asian hominins. One of the most informative early Pleistocene sites is 'Ubeidiya, Israel, which comprises a long lacustrine sequence dated faunistically to ca. 1.4–1.0 Ma (Bar-Yosef, 1998). Stone tool assemblages were mainly found in or on swamp deposits and former lake beaches, as well as in fluvial conglomerates.

Assemblages that lacked bifaces are described as Developed Oldowan, and those with bifaces, or cores that have been flaked on both sides to make an ovate or pointed tool and to remove most of the cortex, are classified as early Acheulean (see Figures 5 and 6). It remains unclear whether these were made by different hominins, or are part of the same lithic techno-complex.

South Asia also has evidence of hominins before 1 Ma. The earliest archaeological evidence is a small stone tool assemblage from Riwat, Pakistan, dated to ca. 1.9 Ma. Recently, Acheulean assemblages at Attirampakkam in South India have been dated to at least 1.0 Ma and possibly 1.5 Ma, and this evidence considerably extends eastwards the Early Acheulean in Asia (Pappu et al., 2011). Finally, the recent and unexpected discovery of simple stone tools from the island of Flores, Indonesia shows that this island was colonised by 1 Ma (Brumm et al., 2010), and probably again at 800 ka (Morwood et al., 1998). Because Flores would have been an island even at times of low sea level, the colonists probably arrived accidentally by drifting on natural rafts of vegetation (Smith 2001).

Early Pleistocene Hominin Subsistence and Settlement

Because animal bones can be associated with stone tools for a variety of reasons (such as stream action mixing the two together, or hominins discarding stone tools in an area previously used by a carnivore), the main evidence for the

subsistence activities of early Asian hominins depends primarily upon the discovery of bone fragments with cut marks resulting from hominins butchering carcasses with stone tools. (As plant remains are preserved only very exceptionally, we know almost nothing about their use of plant foods.) At present,

Figure 3 Stone artifacts from Dmanisi. Bar-Yosef (1998), figure 8.4.

little is known about the hunting or scavenging activities of early Pleistocene Asian hominins. There is no evidence for the use of fire, artificial shelters, or projectiles for hunting. Recent faunal evidence from 'Ubeidiya has been interpreted as showing the butchery and hunting of medium-sized game, although the evidence of hominin involvement in either activity is very slight (Gaudzinski, 2004). The nonhominin faunal remains at Dmanisi are still being studied, and those from sites in the Nihewan basin are too fragmented to allow any meaningful insights about subsistence. Inferences from contemporaneous sites in East Africa suggest that early Pleistocene hominins did not hunt, but obtained most of their meat through scavenging, either passively (i.e., taking whatever a carnivore had left) or actively, by capturing carcasses from carnivores as they were feeding (Dominguez-Rodrigo, 2002). Either possibility underlines the importance of predators in the daily life of early *H. erectus* – either to avoid being eaten, or to obtain meat in a world where competition for it was fierce.

The likely size of the home ranges of early *H. erectus* has been estimated from their inferred height and weight as only

330–430 ha per individual (Antón and Swisher, 2004), or an operating radius of 5.1–5.6 km for a group of 25, which is probably the minimum viable group size. They were thus constrained to environments where the basic necessities of water, animal and plant resources, stone for making tools, and shelter from carnivores could be found within a small area. Small lake basins, such as Dmanisi, the Nihewan Basin, or 'Ubeidiya appear to have been the preferred type of hominin location in Asia; such basins are also ones where the chances of finding their remains are also high (see Asia).

Although hominins were distributed across much of Asia by 1 Ma, their populations were probably largely confined to a small number of refugia, where resources were always plentiful. They were also likely discontinuous geographically and temporally (see Figure 7), because climatic fluctuations between glacials and interglacials every 41 ka after 2.5 Ma (see Pliocene Environments) would have greatly influenced the extent of areas suitable for hominins. Many dispersal events into and within Asia are likely to have been short term and unsuccessful in establishing populations that were permanently resident

Figure 4 Early and middle Pleistocene sites in China.

(Dennell, 2003). Out of Africa 1 – the first movement of hominins from Africa – was probably a series of dispersal events that were not necessarily one-way from Africa to Asia.

Middle Pleistocene Hominin Archives in Asia, 800–300 ka

In the middle Pleistocene, climatic alternations between warm and cold intervals were more pronounced than before, and cold phases lasted much longer, on a 100 ka cycle instead of 41 ka (see [Middle Pleistocene in Eurasia](#)). Sea level changes were more dramatic, with much of Indonesia joined to mainland Southeast Asia and an extensive coastal shelf exposed off China. Major faunal changes also occurred during what is often referred to as the Galerian Faunal Turnover, which led to the emergence of a modern type of mammalian fauna across Siberia, South Asia, and western Asia (see [Mid-Pleistocene of Southern Asia](#)). The middle Pleistocene also witnessed substantial tectonic activity, especially along the forefront of the Himalayas and Karakorum, and the Qinling Range that now divides

North from South China (see [Tectonic Uplift and Continental Configurations](#)). Hominin regional records thus need to be considered against a background of climatic, faunal, and even tectonic changes (Dennell, 2004).

The middle Pleistocene evidence for hominins in Asia is much more extensive than that for the early Pleistocene (see [Figure 8](#)), but is still largely confined to latitudes south of 40° N, although they may have up dispersed to 50° N in Kazakhstan, where, as yet undated, Acheulean bifaces have been found (Vishnyatsky, 1999). There are several middle Pleistocene regional records from Asia, of which the best are from the Levant ([Figure 9](#)), India ([Figure 11](#)), Tajikistan ([Figure 13](#)), the Caucasus and China.

The Levant

There are two ‘flagship’ sites in this region, Gesher Benot Ya’aqov, Israel (Goren-Inbar et al., 2002, 2004), and Latamne, Syria (Bar-Yosef, 1998). The former lies in the Dead Sea Valley. Its deposits are strongly tilted former river- and lake-shore sediments, dated to ca. 800 ka by paleomagnetism. The site

Figure 5 Selected retouched flakes including a scraper, and also core-chopper and a spheroid from 'Ubeidiya. Bar-Yosef (1998), figure 8.9.

contains Acheulean assemblages containing large numbers of basalt cleavers, often made by the Kombewa technique (i.e., from flakes with two opposing bulbs of percussion). The choice of basalt as a raw material, the use of the Kombewa technique, and production of cleavers strongly imply the dispersal of hominins or ideas from Africa, where all these traits occur earlier. In one area of the site, the remains of an elephant skull and a small tool assemblage were found, which has been interpreted as evidence of hunting, rather than the natural death of an elephant in an area where hominins also discarded stone tools. As the site is waterlogged, there is also evidence of plant remains, including charcoal, seed, and nut fragments. According to the excavators, Geshen Benot Ya'aqov contains the earliest evidence for the controlled use of fire, for processing nuts (a highly nutritious resource), and for gathering other plant foods. Faunal evidence indicates that animals were hunted, unlike at 'Ubeidiya, with fallow deer as the main prey (Rabinovitch *et al.*, 2012).

Latamne lies on the banks of the Orontes (see Figure 10). It is probably younger than Geshen Benot Ya'aqov, and is dated to the mid-middle Pleistocene. An area ca. 60 m⁻² was

excavated, within which several hundreds of stone artifacts were found; there was no evidence of structures or fire, and faunal remains were not preserved. Latamne is usually interpreted as a living site, where a group camped while hunting game. Alternatives are that it is a palimpsest of numerous short visits, or a site used seasonally by part of a group.

Another important Levantine Lower Paleolithic site is Berekhat Ram (dated as between 230 and 780 ka) that contains an Acheulean assemblage made from basalt, and an intriguing 'figurine' that is a small piece of volcanic tuff that was intentionally modified. Whether or not this is the earliest example of representational art, it is clearly nonutilitarian, and indicates at least the capacity for some degree of symbolism. Other Levantine sites that are >800 ka are Evron and Bizat Ruhama. The Acheulean at Holon, Revadim, Umm Qatafa, the basal layers (F and G) of Tabun Cave, and Ghamarchi 1b are younger but probably >300 ka (Bar-Yosef, 1998). Although the Acheulean is the most conspicuous part of the Levantine Early Paleolithic, sites such as Bizat Ruhama lack bifaces and contain only flakes and small cores. The final part of the Levantine Early Paleolithic also contains a distinct regional variant known as the Yabrudian.

Figure 6 Acheulean bifaces (1,3,4) and a trihedral (2) from ‘Ubeidiya. Bar-Yosef (1998), figure 8.8.

Figure 7 Discontinuities in hominin occupation in the early and middle Pleistocene of Asia.

This is found over Syria, Lebanon, and northern Israel, and comprises a non-Levallois flake industry with a distinctive convergent (*déjeté*) side scraper. Yabrudian assemblages in layer E of Tabun Cave date from ca. 350 to 250 ka, after which they are replaced by Middle Paleolithic, Levallois-Mousterian

assemblages (see [Global Expansion 300 000–8000 Years Ago, Asia](#)). A recent superlative sequence of Yabrudian deposits at the cave of Qesem in Israel, dated to 400–200 ka, shows that animals were hunted, and butchered by several individuals around hearths (Stiner *et al.*, 2010).

Figure 8 Middle Pleistocene sites in Asia.

Figure 9 Principal archaeological sites in the Levant.

Figure 10 Plan of the 'living floor' at Latamne, Syria. Clark (1969), figure 10.

India

The Indian Lower Paleolithic includes several sites and thousands of bifaces and cleavers, but unfortunately few sites and sequences are dated, and faunal remains are very rarely preserved (Petraglia, 1998). Early middle Pleistocene Acheulean hand axes are known from Dinar and Jalalpur, Pakistan, and Bori, India (Petraglia, 1998) (Figure 11). Apart from a poorly dated but probably Late middle Pleistocene cranial fragment from Hathnora in the Narmada Valley (Cameron et al., 2004), there are no hominin remains from India >30 ka. Nevertheless, a long cave sequence for rock shelter FIII-23 at Bhimbetka from the Acheulean to the Mesolithic shows the persistence of the Acheulean tradition up to ca. 125 ka. Open-air sites are known from Raisen, where more than 90 Early Paleolithic sites were recorded. Best known of all is the remarkable, world-class record from Hunsgi-Baichbal, Karnataka, that contains >200 Acheulean sites (see Figure 12), and a settlement pattern that appears to have been

bipolar, with dry season aggregation camps near water holes, and smaller wet season camps from which plant foods and small game were obtained (Paddayya, 2001). Such is the quality of information from sites such as Isampur that the actions of the hominins that quarried rock to make cleavers can be monitored in detail (Petraglia et al., 2005).

Tajikistan

The loess and paleosol sequence (see Central Asia) of southern Tajikistan, between the Pamirs and Hindu Kush, is another Asian region with an impressive archaeological record (see Figure 13). Sites are always found in interglacial pedocomplexes, a fact that probably reflects the inhospitable nature of the area in glacial periods, as well as the scarcity of stone at times of active loess deposition. The oldest site found so far is Kuldara, in pedocomplex 10–11, and dated by paleomagnetism and correlation with

Figure 11 Principal archaeological sites in India. 1, Riwat; 2, Dina; 3, Jalalpur, Singhi Talav; 5, Dang Valley; 6, Raisen Complex; 7, Bhimbetka; 8, Adamgarh; 9, Durkadi; 10, Chirki-Nevasa; 11, Kukdi; 12, Hunsgi-Baichbal Complex; 13, Attirampakkam. The star represents Hathnora.

the marine isotope record to 855–950 ka (see [Figure 14](#)). The stone tools were made from small (typically <5 cm long) chert and metamorphic pebbles, from which small flakes were obtained (see [Figure 15](#)). There was no standardization of tool types, minimal retouch, or core preparation. Given the size of the raw material, it is unsurprising that hand axes were absent. Later sites, also from interglacial pedocomplexes, are known from Karatau, Lakhuti, and Obi-Mazar, and extend the Tajik record into the Upper Pleistocene ([Ranov, 1995](#)).

The Caucasus

In the middle Pleistocene, several caves were formed that were subsequently used for denning by cave bear (the remains of which virtually dominate most faunal sequences) and occasionally by hominins. Examples are Azyk in Azerbaijan, the caves of Kudaro I, III, and Tconia in Georgia, and Treugol'naya in southern Russia. All except Treugol'naya have Acheulean assemblages containing some hand axes and a few cleavers. ([Ljubin and Bosinski, 1995](#)).

China

In eastern Asia, simple (mode 1) core and flake assemblages continued into the middle Pleistocene, and the type of Acheulean bifaces and cleavers that are so widespread in western and southern Asia are rare. Good examples are the sites of Chenjiaowan (970–900 ka) and Maliang (≤ 730 ka) in the Nihewan Basin ([Chen Shen and Wei Qi \(2004\)](#); see also [Figure 4](#)). Here, analysis of refits, wear analysis, and stone reduction sequences show deliberate selection of high-quality stone, and the progressive reduction of cores by centripetal flaking (see [Figures 16 and 17](#)). Although these assemblages can easily be dismissed as 'simple,' their makers nonetheless exhibited considerable skill in their use of flaking techniques and sequences when making tools for cutting, scraping, and processing meat. The best-known site in northern China is the fissure of Zhoukoudian (formerly Choukoutien) near Beijing, where hundreds of fragments of *H. erectus sensu stricto* were discovered before 1939. The 20 m deep section of locality I, where the main discoveries were made, has recently been re-dated to ca. 700 ka ([Guanjun Shen et al., 2009](#)). It is primarily a record of

Figure 12 Acheulean sites in the Hunsgi-Baichbal Valleys, India. Paddayya (2001), figure 16.1.

the giant hyena, *Pachycrocuta brevirostris*, which accumulated almost all the other bones, including those of *H. erectus*. Hominins also used the cave (hence their artifacts) but there is no clear evidence that they hunted (Boaz et al., 2000).

The same type of core and flake assemblages are found in South China, but the archaeological record is less clear. Sites such as Chenshan and Jigongshan, and hominin remains from Hexian, Nanjing, and Yunxian show that the Yangtze River south of the Qinling Range was occupied from the Early middle Pleistocene (Wang Youping, 2001). Less is known about the middle Pleistocene record of Indo-China and the southern part of China, which were tropical or subtropical, and had a distinctive *Stegodon-Auluripoda* fauna (see [Mid-Pleistocene of Southern Asia](#)). One of the earliest examples is Bose, South China, where large bifaces have been found, some of which look like Acheulean bifaces; these have been dated to ca. 800 ka based on their association with tektites that were part of the fallout from the Australasian Tektite Shower that occurred at that time (Yamei Hou et al., 2000).

At a continental scale, two issues concerning the middle Pleistocene hominin record of Asia deserve attention.

The Movius Line

One of the most durable aspects of the Asian Paleolithic is the distinction first recognized by Movius (1949) between the Acheulean (mode 2) biface assemblages of Southwest and South Asia, and simpler core and flake (mode 1) assemblages of Southeast Asia and China. (The northern boundary of the Movius Line is less distinct, as the Tajik 'loess Paleolithic' is a simple core and flake industry, but bifaces (currently undated) are known from Iran and Kazakhstan.) Although Acheulean-like bifaces are known from Bose in South China and Korea, they are very rare east of the Ganges, compared with the thousands known from India and the Levant. In South and Southwest Asia, the Acheulean is remarkably homogenous (see [Figure 18](#)). Because it is earlier in Africa, its presence in western Asia is widely regarded as the result of the diffusion of ideas or hominins. If so, it seems that neither succeeded in entering China via a corridor north of the Tibetan Plateau, or the more forested regions of Southeast Asia.

Several reasons have been suggested for this division (Schick, 1994). One suggestion is that hand axes and cleavers

Figure 13 Principal archaeological sites in Tajikistan. Paleolithic sites: 1, Kuldara; 2, Obi-Mazar/Lakhuti; 3, Khanako; 4, Chashmanigar; 5, Shugnou; 6, Ogizkuchlik; 7, Karatau; 8, Karamaidan; 9, Khudji. [Ranov and Dodonov \(2003\)](#), figure 1., pp. 133–147.

were not needed in SE and East Asia because bamboo was widely available, and highly versatile as a raw material. Others are that the complex rules for making hand axes were not viable in the forested parts of Southeast Asia; or that hominins beyond the Movius Line did not require an overdesigned way of obtaining a cutting or chopping edge. Another reason may be related to the size of foraging groups; if these were small, there would have been fewer hands to carry bulky items such as bifaces as well as any food that had been obtained. However, it is important to point out that none of the non-hand-axe assemblages studied by Movius from Myanmar, mainland and island Southeast Asia are demonstrably contemporaneous with early and middle Pleistocene bifacial assemblages in South and West Asia, so there is in fact little factual evidence underpinning the original concept of the “Movius Line”.

Middle Pleistocene Hominins: Speciation Events and Isolation?

Three, and possibly four types of hominins inhabited Asia in the middle Pleistocene. In eastern Asia, *H. erectus sensu stricto* was the main hominin type (see [Table 1](#)). By ca. 500 ka, its cranial capacity (one of our few direct indicators of cognitive abilities and body size) had increased to within the

modern human range of ca. 1300 cc, and thus it would have had a greater range of skills and abilities with which to survive. Because *H. erectus* is the only type of middle Pleistocene hominin known from China and Indonesia (excluding Flores), it is possible that the increased severity and duration of cold, glacial periods in the middle Pleistocene may have resulted in hominin populations in eastern Asia becoming more isolated than in the early Pleistocene. The same pattern is probably true of western Asia, although its middle Pleistocene fossil hominin record is almost nonexistent. Western Asia may have been inhabited by a different type of hominin from *H. erectus* and possibly by the ancestor of *H. heidelbergensis*, which is best known from Europe and possibly sub-Saharan Africa. A third type are known as Denisovans, and are known primarily from the ancient DNA extracted from a phalanx and tooth from Denisova Cave, Siberia ([Krause et al., 2010](#)). Its origins are unknown and may be African or Asian ([Martín-Torres et al., 2010](#)). Finally, the earliest inhabitants of Flores are unknown. Some researchers regard the late Pleistocene *H. floresiensis* as an extreme example of dwarfing (here, of *H. erectus*) brought about by isolation; others as possibly derived from a very early form of *Homo*. As with so many other aspects of early Asian prehistory, further research is needed.

Glossary

Acheulean: Name given to an assemblage, or assemblage type, characterized by the presence of handaxes or thinning flakes. First identified at St. Acheul, Abbeville, France.

Assemblage: A collection of artifacts, usually stone tools, but can refer to any preserved material, that is united by a common feature or set of related features. This commonality may be the presence or absence of diagnostic tools. It may, on the other hand, be a particular spatial or temporal boundary that marks the collection of artifacts as discreet. For example, a collection of stone tools from a site/layer which lack a particular type of stone tool might be grouped together and characterized by that absence; alternatively, the layer, or restriction to a part of the site, might impart distinctiveness or discreteness.

Assemblage type: A group of assemblages that share a common feature or features.

Composite tools: Tools made up of two or more different components, often of two different substances. For example, a wooden or antler shaft, with a stone tip.

Cores: A nodule or river cobble of rock that has been shaped by knapping. Flakes have been removed by direct percussion.

Denticulate: A particular type of stone tool usually made on a flake. The edge is retouched to form a ragged and uneven edge when seen in profile. Often described as saw-toothed.

Direct percussion: The process of striking a block of raw material directly with a percussor or hammer (hard or soft).

Fitness indicator: A physical attribute of an animal that stands proxy for a statement on the physical health, genetic quality, social standing, and desirability as a mate of an individual (phenotype).

Flaked flake: A particular type of stone tool made on a flake. This is a flake that has had another flake removed from any edge or off either upper or lower face of the flake. Sometimes the concavity left by the detachment was used, sometimes the spall was used, sometimes both were.

Flakes: The portions of raw material that are detached from a core during knapping by direct percussion.

Formation: A single sedimentary layer, or group of related sedimentary/rock strata having a common feature that unites them. For example, a river terrace may be thought of as a formation, it may be made of one layer of gravel, but it is more likely to be made of a number of different gravel layers interspersed with other layers of sand, silt, or clay.

HandAxe: A stone tool made by shaping a block of raw material, cobble, or big flake. The tool is bifacial – knapped on both upper and lower faces, and the whole is thinned and shaped to a number of different outline shapes. The earliest

are about 1.7 Myr from Africa, and they continued to be in use until the end of the Middle Paleolithic. The process of thinning the handaxe produces a characteristic type of flake – the thinning flake.

HandAx assemblage: An assemblage of stone tools from one layer at a site, as from a number of related layers which contains handaxes or thinning flakes, or both.

Hard hammer or Hammer stone: A pebble or cobble of rock used in knapping by direct percussion, usually cores, but also in the early stages of roughing out a handaxe.

Hominin: A term replacing the older word hominid. It has been adopted because of the genetic work which demonstrates that humans, their ancestors, and related genera, are closer genetically to chimpanzees. But gorillas separated from this group of related genera a long time ago. The old use of the word hominid included gorillas with the human family on the basis that their skeletons showed marked similarities.

Knapping: The name given to the process of controlled breakage of a block of raw material. The process may be employed to shape a block of raw material into a tool. Alternatively, it may be to use the flakes that come off during the process of knapping to make tools from.

Levallois/Prepared core technology (PCT): A way of knapping a block of raw material that carefully shapes and prepares one surface of that block. The resulting core, with its carefully prepared surface, can be used to detach specific types/shapes of stone tool, depending on the particular type of surface preparation applied to the core. The first appearance of Levallois is taken to mark the beginning of the Middle Paleolithic. It may occur at different times in different regions.

Microfauna: Small mammals, such as small rodents.

Middle Pleistocene transition (MPT): The period of time it took for the Earth's orbit to shift from a more circular path around the Sun to a more elliptical one. Prior to the MPT, the glacial–interglacial cycle was dominated by the precessional cycle. The rotation of the Earth around its axis wobbles like a spinning top. The 41-ka precessional cycle is the length of time it takes to complete one rotational wobble. After the MPT, the orbital pattern was more elliptical, and at this time the amplitude and wavelength of the glacial–interglacial cycle changed. The cycle is now more closely tuned to a 100-ka pattern. But whether the orbital eccentricity has been the major factor in causing this change remains unclear.

Non-handAx assemblage: A site, or group of related layers from a site layer from a site, where the stone tool assemblage lacks hand axes or the evidence of their manufacture – the thinning flakes.

Notch: A particular kind of stone tool usually made on a flake. A concavity is made on the edge of a flake by small contiguous retouch removals.

Percussor: A hammer such as a hard hammer stone or a soft hammer such as one made out of bone, antler, or wood.

Retouch or Retouched tools: The process of shaping an edge, usually a flake, in order to make a hand-held tool on a flake. Retouch is usually confined to the flake's edge, and only shapes or sculpts the edge.

Scraper: A particular type of stone tool usually made on a flake. A length of flake's edge is shaped by retouch to make a long continuous retouched edge with a smooth profile.

Soft hammer: Usually made of wood, bone, or antler. These are used in direct percussion in the Lower Paleolithic for the manufacture of handaxes. They are used in thinning and shaping a handax as they take off much less volume of surface raw material during the thinning process than a hammer stone. It is possible that soft rock types can also be used as soft hammers.

Introduction

The middle Pleistocene transition (MPT) represents the period of time between ca. 942 and 641 ka when the Earth's orbit shifted from a more circular to a more elliptical path around the Sun. After this time, the amplitude and duration of Northern Hemisphere glaciations changed markedly when compared to those before the transition (see [Figure 1](#); [Lisiecki, 2005](#); [Lisiecki and Raymo, 2005](#)). Against this climatic backdrop, the hominin colonization and settlement of southern and northern Europe occurred. The MPT makes a useful framework through which this process event can be viewed.

The Pattern of Hominin Colonization of Western Europe

Prior to the MPT

The earliest occupants of Western Europe appear to have arrived either from Africa or from Eurasia. In the former case, they may have represented *Homo ergaster*, or some other small brained species of African *Homo*, moving up the African Rift Valley and its Levantine extension. At the so-called Gates of Europe, the site of Dmanisi, in the Caucasus, represents the earliest Eurasian hominin site with stone tools so far discovered outside of Africa. The site is dated to ca. 1.7 Myr, and the stone tool assemblage was one of cores and flakes – see [Table 1](#). Some of the hominins may have been the prey of hyaena, as a number of the fossils and artifacts were recovered from the infill of their dens. Rightmire and colleagues ([Rightmire et al., 2006](#)) suggest there may be two hominin populations at this site, *H. ergaster* and a large hominin known from a single jaw, *H. georgicus*. Whether this latter was an African hominin, a purely Eurasian species, or a Eurasian descendant of an earlier African migrant remains to be determined. We do not know which hominin was responsible for the manufacture of the stone tools.

South of the Caucasus there are a number of early sites. In the Erq-el-Ahmar Formation, in the Jordan Valley, Israel, sediments are dated to the Olduvai magnetic event at 1.96–1.78 Myr ([Ron and Levi, 2001](#)). Other sediments, some 1.5 km away, but in the same formation, contain cores and flakes. Some researchers are not convinced there are artefacts. Ubeidiya, also in the Jordan Valley, is dated to ca. 1.4 Myr ([Bar-Yosef and Goren-Inbar, 1993](#)). Here a series of handax and non-handax assemblages alternate with each other.

A non-handax assemblage is present at Bizat Ruhama on the southern coastal plain of Israel at about 1.0 Myr.

Another possible crossing point for hominins into western Europe is from the North African coast via the Straits of Gibraltar. Core- and flake-using hominins, presumably *H. ergaster*, were certainly present in North Africa, at sites such as Ain Hanech, at 1.8 Myr ([Sahnouni et al., 2002](#)). The earliest sites in western Europe are the Barranco León 5 and Fuente Nueva 3 localities in the Guadix–Baza basin (previously the Orce sites; [Gibert et al. \(2001\)](#)) in Spain. These have been redated on paleomagnetic, but mostly on faunal, grounds to slightly younger than Dmanisi, perhaps ca. 1.6 Myr in age ([Gibert et al. \(2006\)](#), and references therein). These sites contain core-and-flake assemblages. Also in Spain is a small collection of cores and flakes from levels E9 to E14 at the Sima del Elefante, in the Sierra Atapuerca. They are certainly older than the Brunhes/Matuyama boundary at ca. 780 ka and may be close to ca. 1.0 Myr as indicated by microfauna ([Parés et al., 2006](#)). Contemporary with this, or perhaps slightly younger, are a series of sites at Ceprano, Italy. Small collections of cores and flakes have been recovered and dated between 980 ka and 1.0 Myr.

Whichever species is ultimately shown to be the original colonizer of Western Europe, current evidence does not support an extensive initial migration. [Dennell \(2003\)](#) has argued that first appearances may be deceptive; hominin occupation may represent, in these cases, brief incursions into new areas. Bar-Yosef and Belfer-Cohen have noted that a successful migrant does not always make a successful colonist ([Bar-Yosef and Belfer-Cohen, 2001](#)). The paucity of early sites before the MPT in Western Europe, compared to the stronger hominin signal to the east of the region, remains an enigma (see [Dennell \(2003\)](#) and [McNabb \(2005\)](#) for reviews and references therein). Do the Spanish/Italian data imply a limited, or ultimately unsuccessful, one-off colonization event over the Gibraltar Straits? We do not know.

Across the MPT

Once again a hominin presence on the eastern margins of western Europe is attested to by sites in the Caucasus and in the Levantine Rift Valley. Gesher Benot Ya'akov (GBY) is a handax site on the banks of the Jordan River dated to ca. 780 ka ([Goren-Inbar et al., 2000](#)), and notable for early evidence of the use of fire. The strong similarity between its handax and cleaver component, and those found at contemporary African

Figure 1 Marine Isotope Stages (MIS) and climate curve from combined data stack (LR04) of 57 different records from a global distribution. Data from Lisiecki 2005, and Lisiecki and Raymo 2005. Data used with permission. Horizontal scale is time measured in millions of years (Myr). Vertical scale is delta ¹⁸O record of benthic Foraminifera. Upper diagram shows overall climate change from Dmanisi (1.7 Myr) until the Anglian glaciation (MIS 12) of Britain, herein taken as the boundary between the earlier middle Pleistocene and the later middle Pleistocene – see table 1. The upper diagram makes the point that after the shift to orbital eccentricity (period of change in orbit = middle Pleistocene Transition - MPT), glaciations are colder, and interglacial peaks are warmer. In the lower diagram the climate curve is depicted for the last 1.0 Myr. MIS have been added.

Table 1 Selected stone tool assemblages, and trends in stone tool assemblage types from Europe between 1.0 mya (MIS 28) and the advent of Levallois/prepared core technology (PCT) marking the beginning of the Middle Palaeolithic in Europe. Key to table: NHA = non-handaxe assemblages; A = Acheulean (handaxe) assemblages; BG = Boxgrove; HL = High Lodge; Ar = Arago; StA = St Acheul; SH = Sima de los Huesos; Cep = Ceprano; MP = Monte Poggiolo; TD6 = Atapuerca Trincheras Dolina 6; TD 4 = Atapuerca Trincheras Dolina 4; S. de Elefante = Atapuerca Sima del Elefante; B = Bilzingsleben; V = Vértesszöllös; Sc = Schöningen; K-H = Kärlich H; K-G = Kärlich G; M1 = Miesenheim 1; T = Treugol'naya Cave; GBY = Gesher Benot Ya'aqov; A-G = Amiranis-Gora (Akhalkalaki). Dotted lines indicate period boundaries and their continuation. Double headed black arrows indicate potential date range for individual sites. Single headed black arrows indicate continuation over time. For sources see text citations and references

Acheulean sites, has led some researchers to suggest GBY was a stopping-off point for African handaxe-making hominins migrating up the rift valley. At the Evron Quarry, on the coastal plain of western Galilee, in this case situated away from the rift valley, there are hand axes (found out of context) which date anywhere between the Brunhes–Matuyama boundary and possibly 1.0 Myr (best estimates suggest the earlier end of the range). To the north there is hominin occupation in the Caucasus at sites such as Amiranis-Gora (Akhalkalaki), an open-air site with a core-and-flake assemblage dated on faunal grounds to the Late-early Pleistocene/earlier-middle

Pleistocene transition (see [Table 1](#); see papers in [Lordkipanidze et al. \(2000\)](#)).

There are three, and possibly four, occurrences in southern western Europe, where archaeological sites dating to the MPT are known: two in Spain and two in Italy. The two Spanish examples represent different layers at the same site, the Trincheras Dolina in the Sierra Atapuerca. The lower of the two levels, TD4, represents a small collection of cores and flakes, made on local quartzite, and dated to MIS 22. The higher layer, TD6, is a more significant occurrence ([Bermúdez de Castro et al., 2004](#)). Over 300 stone tools, but no hand axes,

have been discovered. Many of them have been retouched to form scrapers or denticulates. Associated with these artifacts are specimens of a new hominin type, *H. antecessor*. Just as with the Dmanisi hominins, this may be an African migrant, the descendant of one, or a purely Eurasian species, we do not as yet know. To date, no examples of this species have been found outside of southern Europe. Cut marks on the *H. antecessor* bones suggest that this species was a cannibal. Two Italian sites are dated to the MPT. At Ceprano, already noted to have core-and-flake assemblages near the MPT boundary, a skull cap was discovered higher up in the valley sequence than the level of the archaeological sites (Manzi, 2004). Unaccompanied by stone tools, the skull cap may represent a portion of the cranium of an adult *H. antecessor* (Manzi, 2004). Monte Poggiolo, in Italy, is suggested to date from this period; however, uncertainties concerning its radiometric dating, and the clear association of the artifacts with securely dated deposits, have left doubts hanging over this substantial early core-and-flake assemblage (Villa, 2001).

To the north of the Alps, only one site has been securely dated to the MPT. This is the site of Pakefield, Suffolk, England (Parfitt et al., 2005). Flakes and cores have been discovered in sediments of the Cromer Forest-bed Formation. Sediments from this section of the formation date to at least ca. 700 ka (MIS 17). The site clearly demonstrates that earlier phases of the earliest occupation of Europe were not confined to the south of Europe. Associated fauna suggest a warm Mediterranean-like climate.

After the MPT

One thing is clear from Table 1: it is only after the shift to the 100-ka cycle that hand axes appear in the archaeological record of western Europe with any frequency. From this time on, the only hominin present in Europe is *H. heidelbergensis*, whose evolutionary trajectory ultimately led to the Neanderthals. It is tempting to associate the appearance of *H. heidelbergensis* and hand axes with the shift to the 100-ka periodicity. Was the climatic change sufficient to open up previously closed environmental niches and so initiate the movement of animals, and the hominins that preyed on them, into new habitats? Did *H. heidelbergensis* migrate into Europe in one wave, or was it a series of migrations? How was it that this species seemed better able to survive European mosaic environments than *H. antecessor*? Within its suite of adaptive capabilities, what allowed it to cope with European seasonality, and to overcome the difficulties that accompanied overwintering in European environments? At present, we cannot answer these questions. See Roebroeks (2001) for a summary and review.

Throughout western, central, and eastern Europe, assemblages with and without handaxes have been found across a variety of locally variable open-air and cave sites. At present, there is no reason to doubt these were all made by groups of *H. heidelbergensis*. The handax sites are all subsumed under the label Acheulean. The non-handax sites are given a series of names reflecting either regionally significant cultural patterns, or local variations on the non-handax assemblage type. It is a moot point whether these non-handax sites represent distinct cultural phenomena, the result of extended lineages of intergenerational learning, or whether they represent locally variable responses by hominins who normally made hand axes.

For a good review of the Europe-wide variability in middle Pleistocene stone tool assemblages, see Roebroeks and van Kolfschoten (1995).

The frequency of stone tool assemblages in western, central, and eastern Europe, which date to the Later middle Pleistocene (post-MIS 12 glaciation), suggest an increase in population, though the poor degree of survival of older sites should be factored into such interpretations. From the point of view of the stone tool assemblages, however, there is little change in the character of what was made until the wide-scale adoption of Levallois/prepared core technology (PCT), possibly at the end of MIS 9. This date of ca. 300 ka, and the adoption of PCT, is taken to be the end of the Lower Paleolithic and the beginning of the Middle Paleolithic – see Table 1. In some areas, the beginning of the Middle Paleolithic may have been earlier. Many scholars see a link between the handax phenomenon and the rise of Levallois. French archaeologists in particular can track nascent tendencies toward Levallois-like PCT throughout this period (Orgnac 3 (Ardèche) and Baume Bonne (Quinson, Alpes de Haute-Provence; see papers in Tuffreau (1996). Whether this implies geographically distinct multiple local inventions, or alternatively the widespread diffusion of ideas or Levallois-using hominin groups, remains unclear.

Social Construction

Archaeology reveals very few clues that relate to the construction of middle Pleistocene society, by which I mean demonstrating the nature of relationships between individuals, and between individuals and larger groups at a series of hierarchical levels (e.g., personal core group, hunting coalition, family group, whole group, etc.).

Currently, we can only speculate on the nature of relationships between individuals. Artifact analysis may shed some light on these relationships, given the assumption that social signals are encoded within the making, character, and use of material culture. A number of scholars have argued that very large and symmetrical hand axes have little practical use. Rather, they represent social signaling devices aimed at attracting mates (Kohn and Mithen 1999) – in effect the hominin males' substitute for the peacock's tail; as such, they would represent an individual fitness indicator. Much work remains to be done on this aspect of material culture studies.

Gamble (1999) has argued that hominins during the Lower Paleolithic lived in small groups, moving around familiar territories from which they rarely, if ever, strayed. Their knowledge of that territory was acquired through movement along well-known paths and trails. This world, and the hominins' comprehension of it, was dominated by the local and the familiar. Because of a limited linguistic capacity, relations were maintained with individuals via visual signals and the familiarity of often-repeated socially sanctioned gestures and activities. The local group represented the totality of the social world, and contact with other groups in other territories would have been discouraged. Gamble uses the transport of raw stone materials, and finished artifacts whose rock type can be traced to their source, as evidence of the extent of group territories.

Essential to identifying any form of social construction is the presence of language and of the ability to correctly interpret

the intentions and actions of others. Dunbar (2004) has argued that *H. heidelbergensis* at this time was capable of limited grammatical language, and had sufficient cognitive abilities (see below) to empathize to some degree with other individuals. Such abilities would greatly empower socially cooperative action. How much of this would have encouraged a sense of individuality and personality within and between group members is a subject that will engage much future research. See papers in Gamble and Porr (2005).

Subsistence Behavior

The question of how *H. antecessor* and *H. heidelbergensis* acquired their food, and what they ate, is intimately bound with the character of social relations between individuals, sub-groups, and between the sexes. These relationships would have influenced the pattern of hunting and gathering adopted. It may well be that socially and geographically distant groups had very different subsistence practices. There are no *a priori* grounds why a single species-wide pattern need have prevailed everywhere.

At a site in Schöningen, Germany, dated to MIS 11, a series of wooden spears, made of spruce wood, has been excavated in a context strongly suggestive of their use in deliberate hunting. A herd of horses is interpreted to have been mired along the margins of an ancient lake and then killed. Deliberate fires were set along the shoreline, possibly as part of the hunt, possibly for carcass processing and cooking/eating of the meat. Interestingly, this site contained no handaxes. Another wooden spear point of the same date was recovered from the core-and-flake site at Clacton-on-Sea, Essex, England; this one was made of yew wood. Spears are taken to be definitive hunting equipment, whereas stone tools, whether they be the handaxes of the Acheulean, or the sharp flakes and retouched flake tools of the non-handax assemblages, were hand-held carcass-processing equipment, used on the ground (among other things – see below).

At Boxgrove, an MIS 13 site in Sussex, England, hunting is posited on the basis of the successful defense of the carcass of a large species of extinct horse. The extensive cut marks from stone tools left on the horses' bones indicate that the hominins were in no hurry to leave, and they controlled the carcass long enough to extensively butcher it. Rhinoceros bones from this site may show similar evidence. The basis of this assertion is the primacy of stone tool cut marks on the bones. Here a tool has slipped during the process of filleting the meat and removing sinew, cutting into the bone by accident. These marks are overlain by the teeth marks of carnivores, who must then have only gained access to the carcass after the hominins had finished with it. Whether deliberate hunting was involved at Boxgrove, or whether a party of hominins came upon an injured or sick animal that they were able to dispatch with relatively little effort, remains to be proven. The horse butchery was accomplished with the aid of hand axes. Both Boxgrove and Schöningen very clearly imply sufficient social cooperation between individuals acting as a group in order to secure and then defend the carcass against other predators and scavengers. See papers in Gamble and Porr (2005) for more details, and Gamble (1999) for an overview.

By the time of *H. heidelbergensis*, and *H. antecessor*, genus *Homo* was adapted to a predominantly meat-based diet. Only from such a highly protein-rich food source would hominins have obtained sufficient energy resources to survive winter conditions when edible plant resources would have been at a minimum. But the question of how early *Homo* acquired meat remains frustratingly difficult to resolve; was this animal a predator-hunter, or a scavenger, or something in between? The archaeological record is contradictory and fragmented. At the two Spanish sites of Aridos I and II, to the south of Madrid, there is ample evidence of hominins interacting with elephant carcasses. In the former site, bifaces and a small collection of Levallois pieces were found scattered among the bones of the animal. Butchery is strongly implied. In the latter site, the case is similar, except that no Levallois pieces were found. Both assemblages would class as Acheulean. Unfortunately, it was not possible to discern how the elephants died. Two other Spanish sites, in the mountain heartland of Spain, Torralba and Ambrona, were for many years considered good evidence of big game hunting – elephants driven into swampy ground and subsequently butchered. More recent studies set the two sites against a background of occasional visits by hominins to an area not intensively inhabited, thus explaining the low frequency of cut marks and stone tools from the sites. While it can be proved that hominins butchered occasional animals in the vicinity, proactive big-game hunting can not be clearly demonstrated.

As important as meat itself is a supply of fats, which aid in the breaking down of meat proteins. A diet of animal tissue represents the only effective overwintering solution for hominins surviving the cold and resource-scarce winter months and the early spring. Late winter/early spring may have been a time of dietary stress for hominins. Although animals would still have been present, their fat reserves would have been severely depleted over the winter. For hominins, a surfeit of lean meat would have represented a source of poor nutrition without the fat content to break the meat proteins down. Seasonal dietary stress may have been a frequent part of middle Pleistocene hominin life.

While it is an assumption that edible plant material would have formed an important contribution to the diet, just what was eaten, and when, remains unknown. Presumably, the majority of edible plant foodstuffs would be a seasonal, late spring/summer resource. Fish, marine mammals, and birds, may also have contributed to the diet, but as yet there are no substantive data to support the idea that these resources were exploited frequently.

Tool Behavior

Most tractable rock types are capable of being knapped, and were used to manufacture stone tools in the Lower Paleolithic. In regions dominated by fine-grained quartzites, and by siliceous rocks such as flint, these appear to have been extensively used. Knapping involved either the use of a hard hammer stone, usually a cobble, for working cores to make flakes, and roughing out blanks for hand axes, and/or the use of a soft hammer to thin and shape already-worked rough-outs for

hand axes. Soft hammers may have been made of antler, bone, wood, or even softer rock types.

Although there are regional variations on what was made throughout Europe during the Lower Paleolithic, for the most part these represent variations on a small number of basic tool themes. These were handaxes, and their characteristic debitage, thinning flakes; cores knapped for flakes; the un-retouched flakes which could be used as sharp cutting knives; and a variety of retouched tools. The latter were flakes or pieces of shattered raw material whose edges were trimmed by direct percussion along a length of one or more edges. Commonly this trimming was applied to make a scraper, but other retouched tool types were equally as common: notches, denticulates, flaked flakes, etc. As noted above, stone tools were a hand-held processing technology. They were used for carcass dismemberment and processing; usually only the hand axes were removed from a butchery site for further use. The cores, flakes, and retouched tools were left behind. It is only during the Middle Paleolithic that deliberate stone weapon tips begin to appear in the archaeological record.

Materials other than stone were utilized, probably extensively, but the evidence for organic materials is very sparse, a reflection of chance preservation. Shaped wooden spears from Schöningen and Clacton-on-Sea have already been discussed. Schöningen also preserved lengths of wood that have been split, and the discoverers interpreted these as composite tools, the wooden handles into which worked stone items were inserted (Thieme, 2005). Other wooden tools were interpreted as a throwing stick and even a charred cooking stick, used to hang meat over the fire. At a number of sites there are a small number of hand axes that were flaked on fragments of thick bone. They may represent a regionally specific behavioral response to shortages of suitable raw materials since they almost all come from Italy. There is an excellent German example from Bilzingsleben. From Boxgrove, a series of soft hammers (Pitts and Roberts, 1997) has been discovered in antler and in bone. They show extensive wear from use and were clearly used as knapping tools for some time before being abandoned or lost.

The hominin use of fire, its early discovery and the nature of its subsequent usage, has always been surrounded by controversy. But sites like Schöningen and Beeches Pit, Suffolk, England clearly demonstrate the controlled use of fire. Gowlett (2006) argues that hominins may have used fire, and been able to sustain it, but may not have been able to kindle it. As such, it was more of an ecological tool.

What the Archaeology can tell us about Cognition

The material culture of *H. antecessor* is confined to cores and flakes, but the more varied repertoire of *H. heidelbergensis* allows some insights into the cognitive capabilities of this species. To begin with the ability to retain a complicated sequence of thoughts/actions in the memory, and act them out, is implied by the process of cooperative behavior (see above). This is also implied in the ability to conceive of composite tools (see above), especially since they comprise elements of two different media (stone/organic). The enchainment of separate actions and distinct concepts, as part of a

single activity, is further implied in the use of two different hammer types (hard and soft) to make many Acheulean handaxes. The evidence of curated soft hammers from Boxgrove underscores this and implies the capacity for forward planning (Hallos, 2005).

But the signals are contradictory. The curated soft hammers from Boxgrove may have been abandoned when they were worn out, but the spears from Schöningen could certainly have been used again. While some hand axes appear to have been removed from kill sites for later use, a great many perfectly serviceable examples are scattered round the landscape, seemingly abandoned for no particular reason. Was *H. heidelbergensis*' memory/cognitive capacity sufficient only for the immediate task? Or is the paucity of information merely blurring a situationally variable behavioral pattern? Apart from the bone handaxes cited above, and despite the survival of bones on a great number of middle Pleistocene sites, no other bone tools have ever been found. It is worth noting that *H. heidelbergensis* made only handaxes out of bone – no other tool types appear to have been fashioned. Does this actually imply a rather limited cognitive capacity, or alternatively a lack of cognitive flexibility in developing novel solutions for familiar problems, and adapting old practices to new situations?

The Ideational Realm

We have no direct clues as to what early *Homo* in Europe, or anywhere else for that matter, thought about its world, its place within it, and what its relationship to the other world might be – if hominins thought about it all. There are no clear-cut examples of deliberate burials in the middle Pleistocene of Europe. At the Sima de los Huesos, in the Sierra Atapuerca, Spain, some 28, or possibly more, *H. heidelbergensis* individuals were thrown down a deep vertical shaft at the back of the cave. The excavators interpret this as deliberate interment, and cite the presence of a single handaxe found in and among the remains as an example of an offering left among the dead (Bermúdez de Castro et al., 2004). But the hominin bones were found among carnivore remains, and the lower chamber may have been a bear's den with a lower entrance as yet undiscovered. This implies that the hominins' remains were brought in as prey. Even if they were deliberately thrown down the shaft, it may represent nothing more than the disposal of corpses. The case for deliberate interment, and any associated ritualistic qualities, remains to be proved.

There are no examples of Lower Paleolithic artwork in Europe. There are two examples of hominin figurines, one from Berekhat Ram in Israel, and one from outside the area at Tan-Tan in Morocco, associated with Acheulean handaxes (Bednarik, 2003). But in both cases, the resemblance to a human-like figure is questionable, and their interpretation should remain in a suspense account until validated by unambiguous examples.

A sense of the esthetic is often claimed for hand axes which are exceptionally large and which show a clear effort to produce bilateral symmetry. This is a possibility, and these artifacts may have had a distinct social resonance (see above). In other cases, hand axes which have natural holes in the center, around

which the knapper has carefully flaked a working edge along the margins of the nodule or blank, might imply a sense of visual appreciation, or even humor. Hand axes with fossils in the center of the blank or nodule are also sometimes suggested to have been purposefully knapped to emphasize the decorative character of the fossil. But like hand axes with a hole in the center, these are so few and far between that gifting their knappers with a clear sense of their overall esthetic value is difficult. They may well have failed to recognize fossils as having any form of visually pleasing quality, and a hole in the center of a knappable piece of flint may have been nothing more than that.

Conclusion

The archaeological record from the earliest occupation of Europe until ca. 300 ka and the introduction of PCT is a rich and varied one. The European data provide key insights into the variability present in the adaptation and lifestyles of early species of *Homo*. This record is every bit as rich as that found in other parts of the Old World. Future research directives will need to focus on the nature of social behaviour in the middle Pleistocene, and especially the significance of material culture is its social context. Other critical research agendas include the date and character of the earliest occupation of Europe, the question of the relationship between *Homo antecessar* and *Homo heidelbergensis*, and the explanation of non-handaxe assemblages in Europe.

This article is reproduced from the previous edition, volume 1, pp. 99–107, © 2007, Elsevier B.V.

Models of the Geographical Origin of Modern Humans

There were, until recently, two major opposing models for the origin of our species, the out-of-Africa and the multiregional model. Of the two, the latter is now largely abandoned except by a small group of adherents. However, in light of their continued existence in the literature, a summary of the multiregional model is appropriate.

The Multiregional Model

The multiregional model currently holds that *Homo sapiens* evolved in Africa, but, by means of gene flow and hybridization, modern peoples in regions of the Old World retain genetic contributions from earlier hominids: specifically from *Homo erectus* in East Asia and *Homo neanderthalensis* in Europe. The model has two forms. The strong form holds that *H. sapiens* has been the only species of *Homo* since at least 1800 ka, and that the modern form evolved in several places at once, with earlier local populations making substantial genetic contributions to their modern counterparts. The weak form holds that a genetic contribution of some kind was made by local 'archaic' populations to the earliest local modern ones. All proponents of the model have shifted to increasingly weaker forms as new evidence has made the stronger forms increasingly unlikely (Pearson, 2004). Since it is agreed that most (if not all) of the genetic origin of *H. sapiens* is African, the debate has become one of statistically remote possibilities and is essentially over.

The Out-of-Africa Model

The out-of-Africa model, also referred to as the out-of-Africa-2 model (since there was at least one earlier *Homo* exodus from Africa), the African Eve model, or the replacement model, holds that *H. sapiens* evolved only in Africa and then migrated to all other parts of the globe with very little or no genetic contribution from other hominid species, which were rapidly replaced.

Evidence for the Geographical Origin of Modern Humans

Three forms of evidence have been brought to bear on each of these two major models: morphological, genetic, and archaeological. Together, they support only the out-of-Africa model for the origin of our species.

Skeletal Morphological Evidence

Supporters of the out-of-Africa model note continuities in the skeletal morphology of African populations that occur nowhere else. They believe that the earliest modern people

in Europe were morphologically more African than later Europeans, and that any morphological similarities to preceding archaic *Homo* populations outside Africa are the result of convergent evolution under similar environmental stresses or of retained traits from a very ancient common ancestor.

The earliest skeletal materials assigned to *H. sapiens* are all African. The oldest of all *H. sapiens* are the Omo finds from near Lake Turkana, Ethiopia, which have recently been dated to 196 ka (McDougall et al., 2005) (Figure 1). The second oldest *H. sapiens* material comes from near Herto, Ethiopia, and has been dated to between 154 and 160 ka (White et al., 2003) (Figure 1). Specimens from southern African Middle Stone Age (MSA) sites identified as *H. sapiens* include material from Border Cave, Klasies River Mouth (Singer and Wymer, 1982), Die Kelders, and Pinnacle Point 13B (Figure 1). The recent application of multiple dating methods has led to a consensus that at least some of the Klasies and Border Cave material is older than 100 ka and the rest of the Klasies material is older than 60 ka.

In northwestern Africa, Jebel Irhoud (Morocco) yielded several well-preserved fossils, which are almost certainly older than OIS 4 (Hublin, 1992, pp. 186–187), and electron spin resonance (ESR) dates place them between 190 and 90 ka. There are no human fossils of comparable age in northeastern Africa, but modern humans at Skhul and Qafzeh (Israel) are dated to 90–100 ka, are associated with African faunal elements, and have African body proportions. Hublin (1992) considers them to be very similar to those from Jebel Irhoud. They represent a temporary expansion by moderns out of northeastern Africa.

General features such as cranial capacity, tooth size and morphology, and stature, when they can be measured, fall within the range of modern (Holocene) African populations. However, the sample of early *H. sapiens* is still small, so that it is difficult to assess population-scale questions of variability and change. The variability shown has been interpreted both as exactly what would be expected from the founding modern population, and also as having no discernible relationship to living populations.

Genetic Evidence

The genetic evidence strongly supports a single African origin for all living people. This was first applied to modern human origins in a germinal study (Cann et al., 1987) which compared the mitochondrial DNA (mtDNA) from living populations. Cann et al. found that living Africans have the greatest diversity and, thus, the greatest age, and they estimated that all living people are descended from a related group of African women who lived between 200 and 100 ka.

The study was initially attacked as being flawed in methodology. However, since then, many unflawed studies of living

McBrearty and Brooks (2000), Mitchell (2002), and Minichillo (2005).

populations (Pearson, 2004) have reached conclusions very similar to the first study: that our species has a single origin in Africa.

Harpending et al. (1998) utilized both microsatellites on the Y chromosome and mtDNA and found that our ancestors underwent a rapid population expansion about 100 ka. They concluded that the population expansion took place after some bottleneck event, that it occurred in Africa, and that it is completely incompatible with any version of the multiregional model.

Archaeological Evidence from Southern Africa

Skeletal and genetic evidence refers to human biology or anatomy. Archaeological evidence refers to behavior: a profoundly vague concept that includes social relations, customs, technology, language, intellectual capacity, and many other aspects. Within evolutionary biology, it is generally held that if anatomical and behavioral changes do not coincide, then it is the behavioral changes that occur first. In the study of modern humans, however, there has been uncritical acceptance of the idea that anatomical change preceded behavioral. This idea has persisted for over three decades, perhaps because it allows the European record some relevance. However, in the words of

Lewin (1998, p. 113), 'the argument must be recognized as special pleading with no empirical basis.'

MSA studies in sub-Saharan Africa have recently undergone a major paradigm shift, involving reinterpretation of previously known sites and new research goals. For convenience, we name the earlier paradigm that prevailed in MSA studies from the late 1970s until recently, the Klasies paradigm, and the newer one, which has emerged since the late 1990s, the Blombos paradigm.

The Klasies paradigm

The MSA cave sites at the Klasies River Mouth (KRM) in southernmost Africa are crucial to research on modern human origins (Figure 1). Excavated in 1966–68, the MSA deposits there were massive and provided tens of thousands of lithic and faunal artifacts from gross-scale, stratigraphic units. There was also evidence that the oldest deposits were least 120 ka old (Singer and Wymer, 1982). An important pattern in the lithic assemblage was what appeared to be long periods (some 80 ka altogether) without much technological change and near-absence of more modern artifacts, such as fully bifacial points and bone tools (Figure 2). Indeed, the last paragraph of the report includes the dismal statement, 'Most significant is the correlation of such a long period of occupation. . . with little if

anything to show any change in subsistence and economy' (Singer and Wymer, 1982, p. 210).

On the basis of the Klasies sequence, Singer and Wymer outlined the MSA sequence as shown in Table 1, with the Howiesons Poort as the only (very brief) break in the monotony. The Howiesons Poort substage, dating to around 60 ka, includes small-backed blades and true-backed bladelets (Figure 3) that we now know were hafted as parts of composite tools (Figure 4) (Minichillo, 2005). Both backing of lithics and the creation of composite tools are considered to be advanced technologies. The increase in mineral pigment use and color variability during this period has been interpreted as increasingly symbolic behavior (Figure 5).

In 1981, when Volman found that the Klasies sequence did not fit that of Border Cave, he devised the sequence shown in the second column of Table 1. Before long, this proved inadequate as well.

The fauna from Klasies has also played a critical role in discussions of the modernity of MSA people. One such discussion was engendered by Binford's (1984) interpretation, which focused on the relative abundance of parts of animals. He proposed that the MSA people were primarily scavengers and had poor organizational and planning skills. This interpretation has been dismissed on the grounds that the materials he analyzed lacked long bone shaft fragments due to excavation and analytical bias, and because there is now direct evidence for MSA hunting of large bovids.

Other patterning in the faunal assemblages of the MSA continues to be used to construct models of human behavior. Klein (1999) compared the patterns of faunal exploitation in local MSA and LSA sites to argue forcefully that MSA people were inefficient hunters compared with subsequent LSA people. This argument has two parts: first, that fewer species were exploited during the MSA, and, second, that aggressive species, such as adult cape buffalo and bush-pig, were avoided. Klein went on to link this directly to his idea that MSA people lacked some modern intellectual capacities until 50–40 ka. However, a statistical analysis of the same faunal data found that the faunal patterns are poor markers of behavioral modernity, good markers of climatic change at the Pleistocene–Holocene transition, and are better explained by sample sizes and the

application of foraging theory models than by changes in human cognition (Minichillo, 2005).

Within the Klasies paradigm, all models of MSA behavior had to take into account the apparent stasis observed there.

The Blombos paradigm

Blombos Cave ([Figure 1](#)) was excavated using extremely fine-scaled recovery and stratigraphic techniques, and the MSA has precise age-estimates based on single-grain optically stimulated luminescence. The sequence is quite different from that at Klasies, and [Wurz \(2002\)](#) has thus proposed a new scheme for organizing the southern African MSA ([Table 1](#), column 3).

The MSA at Blombos is sealed below a dune dating to 65–69 ka. The uppermost MSA deposits, M1, have yielded bifacial points of the Still Bay type and are sometimes referred to as the Still Bay layers. These have been dated to 74 ± 5 ka ([Henshilwood et al., 2004](#)). Mineral pigments abound, and some engraved pieces of ochre are seen as the earliest expression of symbolic thought. There are also perforated marine shells interpreted as a necklace and, thus, the oldest known personal adornment.

The underlying M2 is best known for the many pieces of worked bone. Careful excavation revealed that the abundant bifacial points in M1 grade into the abundant bone points in M2; that is, two types of artifacts vary inversely. This is quite different from the transitions at Klasies where there were hiatus in occupation between major stratigraphic units.

Recent work at Klasies confirmed the general chronology of the site, but not the specific interpretations. New dates, the lack of climatic change, and low density of shells suggest that the main stratigraphic unit (the SAS Member) was not deposited over tens of millennia, but over a very few millennia or perhaps even centuries ([Minichillo, 2005](#)). This removes the appearance of stasis; the stability within the SAS Member still represents stylistic unity ([Wurz, 2002](#); [Wurz et al., 2003](#)), but for a much briefer period. Rapid deposition has also been suggested for the large MSA deposit at Die Kelders, and technological change within a few millennia is clearly shown at Blombos.

In sum, the MSA archaeological record in southern Africa shows several profound technological changes occurring in periods of no more than a few millennia ([Table 1](#)); Sophisticated and composite artifacts, fine bone-work, use of color and incised patterns, and perhaps even jewelry — these are surely modern behaviors.

The Expansion of Modern Humans

Since there are the remains of early modern humans from the southernmost Cape to Morocco, we know that they expanded throughout Africa. When modern humans began to expand beyond Africa, it was almost certainly from northern Africa, into either Iberia or the Levant. We do not know enough about Arabia to assess the probability of a route through the Horn of Africa. We will outline the archaeological evidence from northern Africa up to 8 ka and then discuss what this reflects about expansion.

Archaeological Evidence from Northern Africa

The great Sahara Desert is the largest and driest desert in the world; very little of it receives more than 25 mm precipitation per annum and some parts receive none at all. At some periods in the past, the Sahara has seen significant rainfall and human occupation extending from the modern sahel to the Mediterranean. During other periods, it has expanded northwards to meet the sea itself, as it does today. Rainfall has always been the most important factor in North African prehistory.

Middle Paleolithic or Middle Stone Age

As in southern Africa, the middle Paleolithic (or Middle Stone Age) of northern Africa probably began by 300–250 ka. It includes two major units, the Mousterian and the Aterian, which overlapped considerably in time. The Mousterian predominates in northeastern Africa and the Aterian in northwestern, but the Mousterian is known as far west as Morocco and the Aterian as far east as the Nile Valley. Within the Nile Valley, other variants have been defined, such as the Nubian complex and the Taramsan, but these are undated. In fact, the only long Middle Paleolithic sequence is from the Haua Fteah, Libya, which was excavated in the early 1950s and is therefore essentially undated.

In artifacts, the Mousterian is very similar to Charentian and Denticulate Mousterian as known in Europe and southwestern Asia, and has a much higher frequency of retouching than is found in southern Africa. Bifacial foliates occur in the Nubian Complex in the Nile Valley and the Red Sea Hills and

also in the Aterian to the west. The Aterian is best known for the presence of tanged tools (not merely tanged points), which are generally taken to indicate hafting. Wurz et al. (2005) concluded that there is the same kind of variability in the MSA technology from Klasies as there is in the Middle Paleolithic of the Nile Valley. However, the latter remains undated and, at this level of technology, convergence is not surprising.

During a warm period about 100–90 ka, the northern African moderns moved briefly into the Levant, as did several other African animals. This colonization failed and the Africans returned south when the climate became colder. The successful and permanent occupation beyond Africa was closer to 50 ka, or later (Hublin, 2000).

There is very little information about when the middle Paleolithic ended. In the Nile Valley, Vermeersch (2000, table 14.1) estimates that the middle Paleolithic ended about 80–70 ka. The Sahara could be inhabited only during periods of increased rainfall, and the last wet period before the final Pleistocene lies far beyond the range of radiocarbon dating. Thus, the end of the middle Paleolithic could be dated only when techniques were developed that extend beyond 40 ka (luminescence, ESR, uranium-series and others). Age estimates for the last wet phase are available for at least seven regions of the Sahara. They range for a low estimate of ≥ 60 ka in the Tadrart Acacus in central Libya to high estimates of ≥ 80 ka in the southcentral Sahara and the region of the Great Eastern Erg. The middle Paleolithic in the Sahara must therefore all be older than 65–70 ka (Figure 6).

There are few reliable absolute dates for the end of the middle Paleolithic. The date of 45 ka at the Haua Fteah is minimal. At Jebel el Gharbi, western Libya, two sites have radiocarbon dates of about 44–43 ka (Garcea, 2004, pp. 33–34). Dating the end of the Middle Paleolithic is particularly contentious in the Maghreb, where the Mousterian sometimes underlies the Aterian. Recent critical compilations of dates for the Aterian (Cremaschi et al., 1998, table I; Bouzouggar et al., 2002, table 7; Close, 2009, table I) indicate that it may not have lasted much (if at all) beyond about 40 ka.

Upper/Late Paleolithic or Late Stone Age

The earliest Upper Paleolithic (in the European and southwest Asian sense) in northern Africa is the Dabban in Libya. It dates to about 40 ka in Cyrenaica (McBurney (1967, p. 326, 1975,

p. 419)) and to about 30 ka in Jebel el Gharbi (Garcea (2004, pp. 33–34)). It is unknown in the Maghreb, where there is no archaeological record between ≥ 40 ka and the first bladelet industry (Iberomaurusian) not long before 20 ka (Figure 7).

The Dabban persisted at Jebel el Gharbi until no later than about 25 ka (Garcea 2004, pp. 33–34). At the Haua Fteah, the only two dates that definitely refer to the Dabban are about 33.1 and 28.5 ka (McBurney 1967, table III.1). The Dabban may have disappeared from both Cyrenaica and Jebel el Gharbi at about the same time, and both areas then remained unoccupied for several millennia.

In the Nile Valley, chert mines date to 35–30 ka followed by a hiatus until about 25 ka (Vermeersch (1992, pp. 121–122)).

At about 20 ka, there was a profound change in technology, to one directed almost exclusively toward the production of bladelets, some of which were then backed. These appeared in Nubia and Upper Egypt at about 20 ka in Cyrenaica by 19 ka, and in the Maghreb before 20 ka at Tamar Hat and Taforalt (Close and Wendorf, 1989) (Figure 7). At the Haua Fteah, the change from the Dabban was so great McBurney (1967) suggested an actual change of population; this would, indeed, be the case if Cyrenaica had been unoccupied for several millennia. The Iberomaurusian certainly represents a new population in the Maghreb, which had been unoccupied for some 20 ka. The Sahara remained uninhabitable. The origin of the bladelet-makers remains unclear but may have been in sub-Saharan Africa.

Epipaleolithic and Neolithic

About 12 ka, the monsoon-belt moved northward and rain came again to the Sahara. For the next 4 ka, all of northern Africa was occupied by descendants of earlier local populations, as far as we know. In the Nile Valley, along the coast and in the Maghreb, freshwater was relatively copious. There were, in addition, the rich resources of the Nile itself and of the Mediterranean. In these regions, therefore, people were able to continue a gathering–hunting–fishing way of life until after 8 ka.

In the desert, however, particularly in what is now the southern Sahara, water was much less abundant – probably less than 20 mm per annum except in mountainous areas – and subsistence was more precarious. People thus ensured their survival as foragers by also keeping domestic animals.

Figure 6 Dates (in thousands of years ago) for the end of the middle Paleolithic in northern Africa. Key: DS = Dar-es-Soltane, GC = Grotte des Contrebandiers (Témara), MA = Mugharet el 'Aliya, IA = Ifri n'Ammar, T = Taforalt (Grotte des Pigeons), BA = Bir el Ater, JG = Jebel el Gharbi, HF = Haua Fteah.

Figure 7 Dates (in thousands of years ago) for the beginning of the Upper or late Paleolithic in northern Africa. Key: T = Taforalt (Grotte des Pigeons), TH = Tamar Hat, BA = Bir Oum Ali, JG = Jebel el Gharbi, HF = Haua Fteah.

Cattle were domesticated in the southern Sahara before 8 ka, but their herders remained essentially gatherer-hunters (Close, 1992). Farming did not become an important factor in northern Africa until the arrival of the southwest Asian domesticated plants and animals, some time after 8 ka.

Routes Out of and into Northern Africa

The archaeological record suggests that between 300 and about 20 ka, northern Africa was sometimes occupied by modern humans and, with the possible exception of the Nile Valley, was sometimes not occupied by anyone. Periods of occupation could be separated by millennia, especially in northwestern Africa. Boats are more recent, so any contact would have to be overland into the Levant, or, perhaps, across the very narrow Strait of Gibraltar.

Although the Strait of Gibraltar is only about 14 km wide at its narrowest point, it is also extremely turbulent and the safest crossing is west of 6° W and ≥ 100 km long. Nonetheless, it is possible to see across the strait today, and, during periods of lowest sea levels, a series of rocky islands would have been exposed, reducing the maximum water crossing to about 4 km (Bouzouggar et al. (2002, figure 23)). The earliest (nonmodern) humans from Iberia almost certainly crossed Gibraltar (Bermudez de Castro et al., 1997), so it is difficult to think that modern humans could not have crossed in the Upper Pleistocene. However, those earliest humans moved into empty territory with no direct competition, whereas until after 30 ka, moderns would have found the hominid niche in Iberia occupied by Neanderthals and their predecessors. In this case, moderns would have been archaeologically visible only if there was a massive invasion of (Hublin 2000, p. 170).

Similarly, only a massive invasion would result in early moderns having a detectable genetic effect in Iberia (Hublin (2000, pp. 170–171)). Today, living Iberians share a common ancestry dating to the Upper Paleolithic, and they are genetically much closer to other West European populations than they are to North Africans. This is the genetic pattern of living populations, so that failure to cross the strait has nothing to do with modernity. Genetic comparison of living people in northern Africa, Europe, and the Levant shows that the oldest European group and the main group in northern Africa (including the Berbers) shared a common Levantine ancestor

until about 50 ka, suggesting that Europe and northern Africa underwent independent colonization by moderns from the Levant. Moderns initially spread from Africa into the Levant by around 50 ka and some of their descendants returned to recolonize northwestern Africa (at least) after it had been empty of people for ≥ 20 ka (40–20 ka).

The Insularity of the Coast of Northern Africa

Modern humans evolved in Africa some 200 ka. Since then and unexpectedly, much of northern Africa has been empty of people for tens of millennia. The discrepancy may lie in our view of northern Africa.

The Arab invaders of the seventh century AD named northwestern Africa *el Jezirat el Maghreb*—the Island of the West (Vaufrey 1955, p. 9) – because it was completely isolated between the Mediterranean and the desert. This isolation is true of almost the entire coast of northern Africa and its prehistory becomes more understandable when it is viewed as a series of islands (Shaw (2003, p. 98)): the Nile Valley, Jebel el Akhdar, Jebel el Gharbi, and the Maghreb (Figure 8). The islands have permanent sources of drinking water and are separated from each other by hundreds of kilometers of coastline, where the Sahara meets the Mediterranean and drinking water is rare to lacking.

During wetter phases, the islands were easily accessible from the rest of northern Africa and most of what is now desert was occupied. During phases of aridity, contact between the islands is very unlikely and each would become isolated. By 40 ka, human occupation had ceased, certainly in the Maghreb, probably in Jebel el Gharbi and perhaps in Cyrenaica. We conclude that, in each area, modern humans may have become locally extinct.

The presence of the Mediterranean and the absence of boats meant that any travel between the islands of northern Africa had to be overland. Historically, such journeys have depended upon the use of domestic animals. There were no domestic animals on the coast (although they existed in the southern Sahara) until after 8 ka and people had to carry everything they would need themselves, especially water.

Nevertheless, inter-island journeys were sometimes made successfully and islands could be recolonized for periods of millennia. Thus, about 40 ka, the makers of the Dabban

Figure 8 Northern Africa seen as a chain of islands. The boundary between the desert and the sea is deliberately blurred because its precise location is not crucial, and the islands remain insular no matter what the sea level.

reached Cyrenaica from the east and remained there until well after 30 ka. Their descendants (presumably) can be seen as far west as Jebel el Gharbi till about 30 ka; the area was occupied until about 25 ka. But they seem not to have gone farther west into the Maghreb. The final colonization of the islands began somewhat more than 20 ka with the makers of the backed-bladelet industries; modern human beings have occupied all of the islands ever since then.

Global Expansion 300 000–8000 Years Ago, Asia

Transitions in Lithic Production after 300 ka

In western Asia (including the Caucasus), changes in lithic production resulted in the type of Mousterian industries seen in Europe, whereas changes were more muted in southern Asia, and resulted in a non-Mousterian Middle Paleolithic. In China and the Far East, changes were even more subtle, and stone tool assemblages continued without major industrial innovations. Outside the Levant, details are still sketchy as to when and how these late middle Pleistocene transitions occurred.

The Lower to Middle Paleolithic transition in the Levant occurred ca. 250 ka (Shea, 2003) (Table 1). The immediate precursor of the Levantine Mousterian is the Yabrudian industry, which dates from 350 ka, and is the earliest regional lithic variant in Asia. It is found in Syria, Lebanon, and northern Israel, and features steeply retouched scrapers and relatively thick flakes (Figure 1); the Levallois technique is absent, and bifaces are rare or absent. The principal Middle Paleolithic industry of the Levant is Mousterian. Its most conspicuous attribute is the use of recurrent Levallois core reduction strategies to produce triangular and subtriangular flakes. The earliest Mousterian lithic assemblages are distinctive, with high values for Levallois and laminar indices. The transition from hand-held handaxes in the Lower Paleolithic to the use of hafted tools (i.e., stone points or blades mounted on wooden shafts) in the Middle Paleolithic may be considered a profound technological shift, as later hominids employed stone projectile weaponry to obtain game (e.g., Shea (2003)). Early Mousterian industries in the Levant range from ca. 250 to 128 ka, thus including a transition from warm and humid conditions during oxygen isotope stage (OIS) 7 to colder and more arid conditions in OIS 6. It is not clear which hominin(s) made the earliest Levantine Middle Paleolithic tools because both Neanderthals and early modern humans in the Levant are associated with the same types of Middle Paleolithic assemblages.

The Lower to the Middle Paleolithic transition in South Asia is poorly dated, though there is good stratigraphic evidence to indicate that the transition from large bifacial industries of the Acheulean to prepared core and flake industries of the Middle Paleolithic occurred by ca. 150 ka (Misra, 2001; Petraglia et al., 2003) (Figure 2). Acheulean industries in India may have been made by *Homo heidelbergensis*, based upon the identification of a cranial fragment from the Narmada river valley (Cameron et al., 2004). The hominin(s) that made the stone tools associated with the Indian Middle Paleolithic remain unknown but likely to have been *H. sapiens* by at least 60 ka (Mellars, 2006), if not earlier (Petraglia et al., 2007; Clarkson et al., 2012).

The Early Middle Paleolithic in Central Asia is poorly dated, but those from the last glaciation are Mousterian, or have Mousterian affinities. Several caves in Uzbekistan, notably Obi Rakhmat (ca. 60–90 ka), Anghilak (ca. 36–45 ka), Khudji (ca. 40 ka), and Teschik-Tasch, show that Neanderthals were

present in OIS 4–3 (Glantz et al., 2008). The best-dated Early Middle Paleolithic assemblages are from Tajikistan and Uzbekistan; these date from OISs 5 and 7, and show an increase in Levallois flaking. Their makers are unknown, but likely Neanderthal.

Although a Middle Paleolithic has been recognized in China on the basis of stone tools classifiable as scrapers, points, and choppers, these assemblages are so similar to earlier ones that it is doubtful whether it is useful to regard them as Middle Paleolithic rather than a later variant of the Early Paleolithic (Gao and Norton, 2002). Additionally, very few Chinese sites are sufficiently well-dated and -documented to allow detailed analyses of the changes that occurred between 300 and 50 ka. The best-documented late middle Pleistocene site in China is currently the cave of Panxian Dadong (ca. 100–250 ka) in southern China (Miller-Antonio et al., 2004); although lithic reduction sequences were complex, they were not dependent upon the type of prepared-core technologies so common in western Asia.

The Emergence of the Upper Paleolithic and the Expansion of Modern Humans

The earliest specimens of anatomically modern humans (AMH) in Northeast Africa date from ca. 190 ka, and are assumed to have originated in that continent. By ca. 25–30 ka, AMH is the only type of humanity in mainland Eurasia, and its expansion at the expense of indigenous populations (encapsulated by the 'Out of Africa 2' model) was a complex, lengthy, and still very poorly understood process (Dennell and Petraglia, 2012). The main archaeological change that occurs across much of Asia as part of this process is the replacement of Middle Paleolithic assemblages by Upper Paleolithic ones. The relationship of these changes to the expansion of modern humans is not clear-cut: in the Levant, for example, the Later Middle Paleolithic was made by both Neanderthals and modern humans, and early Upper Paleolithic assemblages are far from being unambiguous indicators of modern humans. Additionally, the quality of regional records of this process generally declines from west to east across Eurasia.

The Levant

The Israeli caves at Mount Carmel have yielded extensive fossil material of Neanderthals and anatomically modern humans (Shea, 2003). The cave sites of Tabun, Kebara, and Amud have yielded Neanderthals, whereas Qafzeh and Skhul contain anatomically modern humans, of which the earliest date to ca. 100 ka. This date is widely regarded as indicating the time when modern humans first entered Asia from Africa; however,

Table 1 Periodization of the Levantine Middle Paleolithic (after [Shea 2003](#): Table V)

Period	Dates (ka)	Marine OIS and Levantine climate	Hominins	Lithic industries
Late Lower Paleolithic	350–250	OIS 8–7. Cold, then warmer	<i>Homo</i> sp.	Late Acheulean and Acheulo-Yabrudian
Early Middle Paleolithic	250–128	OIS 7–6. Warm, then colder	<i>Homo</i> sp.	Phase 1 Levantine Mousterian
Mid Middle Paleolithic	128–71	OIS 5. Initially warm and hyperarid but growing colder, more humid	Neanderthals and early modern humans	Phase 2 Levantine Mousterian
Late Middle Paleolithic	71 to <47	OIS 4–early 3. Cold and dry	Neanderthals	Phase 3 Levantine Mousterian
Initial Upper Paleolithic	47–32	Mid-late OIS 3. Cold and dry	Modern humans	Early Upper Paleolithic (Emiran and Ahmarian), possible late Levantine Mousterian

given that there is no hominin skeletal data in western Eurasia between 100 and 300 ka, an earlier date cannot be excluded. Dated specimens of Neanderthals indicate that they were present in the Levant at and probably between 120 and 60 ka. Although the dating evidence implies that moderns and Neanderthals coexisted in the same region, it is of course possible that they never met, as different populations could have expanded during particular climatic phases, the Neanderthals occupying the region during colder periods, and the moderns during warmer episodes. The presence of both Neanderthals and modern humans in the region does however support the single-origin model of human evolution, as Neanderthals clearly became extinct in the Later Pleistocene ([Stringer, 2002](#)).

Significant technological changes occur at ca. 47–45 ka in the Levant, and early Upper Paleolithic industries occur in Ksar Akil (Lebanon) and Boker Tachtit (Israel) at around 45–38 ka. Two later Upper Paleolithic assemblages, known as the Ahmarian and the Aurignacian, are dated to ca. 38–30 ka. The Ahmarian is characterized by a blade and bladelet industry whereas the Aurignacian consists of a flaked-based industry with lamellar retouch on carinated scrapers and burins. The latter type of assemblage may have originated in Central Asia or in western Iran, and is generally regarded as the earliest unequivocal Upper Paleolithic tradition in Europe. Though these earliest Levantine Upper Paleolithic assemblages are not associated with human fossils, it is generally assumed that they were produced by modern humans ([Bar-Yosef, 2002](#)).

Anatolia and the Taurus-Zagros Mountains

Beyond the Eastern Mediterranean of the Levant, Neanderthals lived in the Taurus-Zagros Mountain zone, the Caucasus, and Central Asia as far east as the Lake Baikal region, Siberia ([Krause et al., 2007](#)). The Middle Paleolithic industries of this region are differentiated from those of the Levant as they often have low Levallois indices, little centripetal core preparation, and few retouched tools. One of the Neanderthals from Shanidar Cave, Iraq, has signs of disease and numerous injuries, perhaps indicating that this individual was cared for by others. The Baradostian industry, dating to ca. 40–35 ka, directly overlies Mousterian assemblages in cave sites of Iran and Iraq. The Baradostian is characterized by high percentages of burins, and rare carinate scrapers and busked burins, reminiscent of European and Levantine Aurignacian assemblages. The Mousterian assemblages in Karain Cave of western Turkey contain high

frequencies of retouched and resharpened tools, including side-scrapers, points, and convergent scrapers of nonlocal materials ([Kuhn, 2002](#)). The assemblages are primarily discoid, though Levallois technology appears in at least one stratigraphic layer. The Karain assemblages are thought to have affinities with the Zagros Mousterian or the Middle Paleolithic of the Balkans and southeastern Europe, rather than the Levant.

Upper Paleolithic sites are generally rare in elevated zones of the Zagros, the Iranian plateau, and the Anatolian plateau, leading some investigators to wonder if gaps in the archaeological records indicated abandonment during OISs 2 and 3. Few have been intensively studied and/or dated, and the Middle to Upper Paleolithic transition in this region is still poorly understood. Üçağızlı Cave is an early Upper Paleolithic sequence in Turkey that has yielded a combination of typical Middle and Upper Paleolithic tools that have been dated to ca. 40 ka ([Kuhn, 2002](#)) ([Figure 3](#)). The forms include end-scrapers, burins, and retouched blades, many pieces classifiable as Levallois flakes, blades, and points. The upper layers contain assemblages that are similar to early Ahmarian ones, including a prismatic blade technology dating to between 33 and 28 ka. Bone tools are common and the assemblages contain shell ornaments. Epipaleolithic or late Upper Paleolithic assemblages with microlithic-backed pieces have been reported throughout the region. The number of sites and the diversity of ecological niches exploited suggest localized specializations involving hunting of particular species.

South Asia

Further eastward, South Asia contains numerous Middle Paleolithic sites, but these are not associated with any human fossils ([Misra, 2001](#); [James and Petraglia, 2005](#)). During the Middle Paleolithic, there does not appear to be a single or favored technique of core preparation throughout the Indian subcontinent, though Levallois and discoidal techniques are most often described. As in Southwest Asia outside the Levant, there is urgent need for more well-dated sequences between 125 and 25 ka. From approximately 45 ka, increases in blade production and variability in assemblage composition characterize the South Asian record, with assemblages divided into flake-blade, blade-based, and blade and burin industries ([Murty, 1979](#)). Microlithic industries are as old as 36 ka, indicating that they were part of a diverse late Paleolithic package ([Clarkson et al., 2009](#); see also [Figure 4](#)). In sites such as Patne,

Figure 1 Transitional Acheulo-Yabrudian assemblages from Qesem Cave, Israel, dated to about 300–200 ka. (a) Handaxe; (b) radial core (1), cores on nodules (2, 3); (c) side-scrapers (4–6). geometric microlithic technology developed from an industry characterized by backed blades and burins (Sali, 1989) (Figure 5). With the exception of the geometric microliths, the standardization of retouched artifact forms is not comparable to those seen in the Upper Paleolithic of Europe or Western Asia. There does not appear to be a sudden shift to ‘classic’ prismatic cores at the onset of the late Paleolithic, but rather, there is contemporaneity between flake- and blade-based technology, with the introduction of microlithic industries by 36 ka (Petruglia *et al.*, 2009). There is some evidence

for deliberate construction of shelters by about 45 ka and some evidence for symbolism after 28.5 ka, though the evidence is rare (James and Petruglia, 2005).

Eastern Asia

Late middle Pleistocene hominins such as the Dali and Jinniushan specimens have been classified as archaic *Homo sapiens* (Wu and Poirier, 1995), late *H. erectus* (Thorne and Wolpoff, 1992) or even as *H. heidelbergensis* (Rightmire, 2001), on the grounds that they are intermediate (at least chronologically) between *H. erectus* and *H. sapiens*. Discussion is often obfuscated by lack of agreement over what constitutes an ‘archaic’ or ‘modern’ feature, or suite of features. Further evidence is clearly needed to clarify what was probably a complicated set of biogeographic and phylogenetic relationships in eastern Asia (Lahr, 1996). As a further complication, some Chinese specimens may be “Denisovan”: this type of hominin is likely related to Neanderthals but known only from the ancient DNA that was extracted from a phalange and tooth from Denisova Cave, Siberia (Krause *et al.*, 2010).

Late Paleolithic Far Eastern lithic artifact assemblages vary in reduction techniques, and include bipolar flakes, Levallois blades, and microliths (Jia and Huang, 1985; Brantingham *et al.*, 2001) (Figure 6). The Zhoukoudian Upper Cave, which is associated with modern humans, contains an assortment of elaborate artifacts, including bone needles and harpoons, perforated marine shells, stone beads, and grave goods in burials. The association of modern humans with symbolic artifacts may indicate their spread, and the replacement of archaic hominins. Microlithic artifacts, perhaps as old as 28 ka, occur in a variety of ecological settings, from deserts to lakeside settings, indicating a wide range of adaptations.

The Replacement of Indigenous Populations of Neanderthals, *H. erectus* and *H. floresiensis* by Modern Humans

The prevailing view among many geneticists and paleoanthropologists is that all living humans in Asia today are descended from a relatively small population which originally arose in Africa (e.g., Ingram *et al.* (2000)). Based on slight and generally ambiguous fossil and archaeological evidence, it has been argued that modern humans reached the Levant by 100 ka, and later, other populations traveled (perhaps along the Indian Ocean rim) to reach Australasia by 45–60 ka (Lahr and Foley, 1994; Field and Lahr, 2006) (Figure 7). An alternative scenario is that our species entered the Levant and Arabia by OIS 5 (Petruglia *et al.*, 2011). Whichever model is preferred, modern humans replaced Neanderthals in Southwest and Central Asia, indigenous populations (type(s) unknown in South Asia), populations of *H. erectus* in Eastern Asia, and ultimately, *H. floresiensis* in the island of Flores, Indonesia.

The appearance of anatomically modern humans in Africa is accompanied by a variety of economic, social, and symbolic traits that are often associated with modern human culture, although the materialization of such traits is temporally and geographically patchy over the last 250 ka (McBrearty and Brooks, 2000), and few of these traits are both widespread and exclusive to modern humans.

Figure 2 Landscape relations between transitional Lower and Middle Paleolithic assemblages from Lakhmapur, Malaprabha Valley, India. (a) Prepared cores in early Middle Paleolithic assemblages are associated with (b,c) diminutive hand axes and cleavers. (a) Adapted from Petraglia MD, Schuldenrein J, and Korisettar R (2003) Landscapes, activity, and the Acheulean to Middle Paleolithic transition in the Kaladgi Basin, India. *Journal of Eurasian Prehistory* 1(2): 3–24.

The period between 45 and 30 ka in the Levant is marked by the extinction of the Neanderthals and the expansion of modern humans equipped with Upper Paleolithic adaptations (Shea, 2003). Neanderthals throughout western and Central Eurasia appear to have been well-adapted to temperate woodlands and cold steppes, with adaptations geared toward meat acquisition. Economic intensification in later Neanderthal adaptations in the Levant are indicated by multiseasonal site occupations, a broadening of the subsistence base, and production of spear points to procure prey (Shea, 2003). Though Neanderthals may have had complex social and economic behaviors, small behavioral and adaptive advantages on the part of modern humans may have eventually led to their replacement by modern humans.

In addition to the expansion of modern humans into the Levant, populations may have used the Bab al Mandab strait

across the southern end of the Red Sea for expansions during OIS 5, as is exemplified by the presence of Middle Paleolithic sites in southern Arabia with Northeast African affinities (Petraglia and Alsharekh, 2003; Rose, 2004). Though it is clear that modern humans reached Australia by 45–42 ka and possibly earlier (Bowler et al., 2003; O'Connell and Allen, 2004), the spread of modern humans across Asia has not been documented from skeletal evidence or archaeological assemblages, and remains at present a hypothesis based largely on modern genetic evidence. Y-chromosome and MtDNA data suggest the colonization of South Asia by modern humans originating in Africa, sometime between 73 and 55 ka (Kivisild et al., 2003). The genetic data suggest a single, early migration was responsible for the initial settlement toward South Asia and toward the east (Thangaraj et al., 2005). It has been suggested that modern movements into South Asia may have

Figure 3 Early Upper Paleolithic artifacts from Üçağızlı Cave, Turkey. Ahmarian (1–4) and initial Upper Paleolithic (5–8) tools. Adapted from Kuhn SL (2004) Upper Paleolithic raw material economies at Üçağızlı cave, Turkey. *Journal of Anthropological Archaeology* 23: 431–448, figure 3.

originally been accompanied by a Middle Paleolithic technology, presenting problems in discriminating such assemblages from those being used by resident populations of archaic hominins (James and Petraglia, 2005). Though modern humans were probably present in South Asia sometime after 70 ka, evidence for modern human behavior develops slowly and such signs are temporally and spatially patchy. Because stone tool assemblages in India before the great Toba volcanic eruption of 74 ka are similar to subsequent ones that were likely made by *H. sapiens*, it is possible that our species was already in South Asia before 74 ka (Petraglia et al., 2007). The development of new cultural innovations in the Late Paleolithic of South Asia may be related, in part, to fluctuations in the environment and demographic changes, indicating that it may be difficult to discern movements of modern humans. Modern humans probably reached east and south Eastern

Figure 6 Initial Upper Paleolithic assemblages from Shuidonggou, China (adapted from Brantingham *et al.* (2001), figure 5). Flat-faced 'Levallois' cores (1–2); Levallois blades (3–4); retouched flake-scraper (5); side-scraper (6).

Asia by 40 ka, as indicated by the remains of modern humans at Tianyundong Cave, North China (Shang et al., 2010) and Niah Cave, Borneo (Barker, 2002), both dated at ca. 40–43 ka. Even earlier indications of *H. sapiens* in East Asia include a metatarsal from Callao Cave, the Philippines (Mijares et al., 2010) and a cranium from Tam Pa Ling, Laos, that has been directly dated at ca. 63 ka (Demeter et al., 2012). Though encounters between archaic and modern humans are unclear across most of Asia, the replacement of indigenous archaic populations was probably completed by 18 ka, with the extinction of hominins such as *H. floresiensis* (Brown et al., 2004) in remote island settings. In Java, *H. erectus* may have been extinct before the arrival of *H. sapiens*, as the Ngandong assemblage of *H. erectus* has recently been re-dated to 143–546 ka (Indriati et al., 2011).

The Colonization of New Territories after 125 ka

Before the last interglacial, hominin populations inhabited the same parts of Asia as had been colonized in the middle Pleistocene, that is, up to ca. 40–45° N, with perhaps short forays further north when climatic conditions permitted. As with so much of early Asian prehistory, more dates are needed to indicate when and how the expansion of humans across the whole of Asia occurred. Neanderthals in Central Asia appear to have been the first to expand northward into southern Siberia up to 55° N, probably in the early part of OIS 4 in the last glaciation, and possibly earlier. This process of colonization accelerated after 40 ka, and was most likely accomplished by modern humans, which colonized the Japanese islands by 40 ka (most likely by sea), and began to colonize areas >55° N after 26 ka (Goebel, 1999). Modern humans rather than

Figure 7 Potential routes of anatomically modern humans during OIS 4, showing routes and barriers. Adapted from Field JS and Lahr MM (2006) Assessment of the southern dispersal: GIS-based analyses of potential routes at oxygen isotopic stage 4. *Journal of World Prehistory*, figure 14.

H. erectus may also have colonized the rainforest regions of SE Asia. Finally, the Tibetan Plateau, 5 million sq km in extent and averaging 5000 m a.s.l., was uninhabited until the Late Glacial, and was one of the last parts of Eurasia to be settled (Brantingham et al., 2001).

Settling and Sedentism: Developments after the Last Glacial Maximum

Major changes in subsistence occurred after the Last Glacial Maximum, ca. 16–18 ka, and resulted in the emergence of agricultural societies across much of Asia by 8 ka BP (Mithen, 2003). The background to this process was the ending of the last Ice Age and onset of modern climatic conditions. In Southeast Asia, the most conspicuous environmental change was the flooding of the Sunda Shelf, which resulted in the loss of >1.5 million sq km of land, or three-quarters the present day area of mainland Southeast Asia (Voris, 2000). The archaeology of foraging populations in the Levant between 20 and 14 ka is relatively well known (Bar-Yosef, 1998). The Kebaran is characterized by obliquely truncated blades, bladelets, and microliths, with the addition of groundstone implements, perhaps used to process nuts and grasses. The Kebaran is thought to reflect seasonal mobility by hunting and gathering groups between highland and lowland settings. Ohalo II, on the

shore of the Sea of Galilee of Israel, is a spectacular waterlogged site dated to ca. 20 ka (Nadel, 2002). A community geared toward fishing and hunting-gathering left behind brush huts, hearths, hundreds of thousands of charred seeds/fruits, and fish and animal bones (Figure 8). During a humid interval at around 14.5–13 ka, an expansion of settlement occurs into the interior and highland zones of the Negev, Sinai, and southern Jordan. Climatic improvement appears to be responsible for population expansions into the steppes and desertic areas.

The date of 11 ka BP is usually given as the beginning of food production based on the domestication of relatively few wild plant and animal species (Diamond and Bellwood, 2003). Until the end of the Pleistocene, all people in Asia lived as hunter-gatherers. The introduction of food production led to major changes in subsistence and settlement practices in some populations, whereas in other populations it led to territorial marginalization or to even to extinction. Some foraging populations continued to live alongside Neolithic peoples, sometimes engaging in trade and exchange with settled groups.

The emergence and subsequent expansion of Natufian populations in the Levant is dated to about 13–10 ka (Bar-Yosef, 1998) (Figure 9). Some large sites, such as Ain Mallaha, hint at prolonged occupations based on substantial semi-subterranean dwellings and multiple superimposed occupation floors. Stone tool assemblages include numerous crescentic microliths and bone, and horncore tools include

Figure 8 Ohalo II excavations, showing (a) hut remains and (b) human skeleton. Photographs by D. Nadel.

harpoons, fishhooks, spear and arrow points, awls, and needles. Large groundstone querns are often times found and may have functioned in the processing of nuts or cereals. The availability of cereal grasses and semisedentary lifestyles were likely major contributing factors in leading to agriculture. The Pre-Pottery Neolithic witnessed an increase in the number and diversity of sites, and changes in settlement patterns may be partly a reflection of climatic changes occurring between 11 and 10 ka (Bar-Yosef, 1998). Abu Hureyra, located in Syria and occupied from about 11.5 to 7 ka, is a good example of changes in lifestyle and economy that occurred over this period (Moore et al., 2000). The first period of habitation, before agricultural development, included a settlement that appears to represent year-round occupation. The populations gathered a variety of wild seeds, including cereals, and hunted migrating gazelle populations. After about 10 ka, Abu Hureyra was inhabited by permanently settled communities who had cultivated and processed a variety of domesticated seeds, such as oats, barley, chickpeas, emmer, and lentils. Such changes in Pre-Pottery Neolithic communities were precursors to more significant technological, social, and economic changes that were to take place throughout Western Asia.

By 13–8 ka, many parts of Asia were filled with complex hunting and gathering communities. Siberia, which was largely uninhabited during the Last Glacial Maximum, was rapidly recolonized up to the Arctic Ocean by 12.5 ka (Goebel, 1999). After 12.5 ka, Jomon sites in Japan appear to show production of pottery and sedentary lifestyles based on fishing, with supplementation of cereal grains by around 9 ka. Mesolithic sites are well represented in the Indian subcontinent, leading archaeologists to infer that the large number of sites relates to marked growth in human populations (Misra, 2001).

Figure 10 Map showing Epipaleolithic and Mesolithic sites of the central Ganga Plains. Adapted from Chattopadhyaya UC (1996) Settlement pattern and the spatial organization of subsistence and mortuary practices in the Mesolithic Ganges Valley, north-central India. *World Archaeology* 27(3): 461–476, figure 1.

The increased food supply available in the Mesolithic is thought to have led to a reduction in mobility, as reflected in the large size of sites, evidence for huts and communal hearths, the substantial appearance of habitation deposits, and the presence of cemeteries, particularly in the Ganga Valley (Chattopadhyaya, 1996) (Figure 10).

Recent archaeological evidence suggests two distinct centers of early rice cultivation in Asia (Fuller, 2007). In China, it is widely accepted that rice cultivation was underway in the Middle Yangzi, and adjacent South China by 8 ka, and in India, rice cultivation may date back to as early as ca. 9 ka. While further research is needed in South Asia, the recent evidence indicates at the very least that foragers were exploiting wild rice from about 9 ka. In northwestern South Asia, the dominant crops from the time of earliest evidence derived from the Southwest Asian Neolithic founder crops. Representatives of this crop package spread to western Pakistan by the time of Neolithic Mehrgarh after 9 ka (Jarrige et al., 2006), and

Central Asia by ca. 8 ka. Such subsistence and settlement shifts set into motion fundamental changes in the demography, health, and lifestyles of populations inhabiting Asia.

Glossary

Artifact: Any object shaped and made by humans

BP: Radiocarbon years before the present, conventionally measured from 1950

Obsidian: A natural glass produced from erupting volcanoes. Molten rock ejected from the crater solidifies extremely rapidly prohibiting the growth of crystals and forming glass

Luminescence dating: A method of dating inorganic material like clay and sediments. Electrons

built up and trapped in the crystal lattice structure of quartz grains are artificially stimulated by light that releases them. The amount of energy given off is an indication of how long these sediments have been buried

Taphonomy: Study of the laws of burial, particularly transformation of organics from the biosphere to the lithosphere

Introduction

The human colonization of the Sahul landmass, the continent that joined New Guinea, Australia, and Tasmania after dry land was exposed due to lowered sea level, was a significant event in our species global expansion. It heralded the first sea crossing by peoples whose ancestors spread out of Africa perhaps 70 000 years ago (ya). It would have involved the construction of water craft sophisticated enough to make voyages of up to 100 km from Timor and lesser distances through the Indonesian archipelago. Clearly, organizational skills and language must have been present to make such trips. Crossing this water gap brought people into a world that, in some respects, would have been familiar while in others unique. Many plants would have been recognizable especially rainforest varieties, as well as marine life but most animals encountered would have been alien to them. On passing through the biogeographical transitional zone of Wallacea and across Lydekkers Line, which forms the faunal boundary of the Australian region, people entered a land of giant marsupials, egg-laying mammals, giant flightless birds, and enormous reptiles (Figure 1).

Unlike the Eurasian fauna human groups would have co-existed with, there were no large carnivorous pack animals such as hyenas or wolves. Large cave bears and felids were absent as were smaller carnivores like the fox (until European settlement), wolverine, and lynx. Only three marsupial carnivores were present, the thylacine (*Thylacinus cynocephalus*), Tasmanian devil (*Sarcophilus harrisii*), and the marsupial lion (*Thylacoleo carnifex*), the former two surviving across the continent until about 3000 years before present (BP) and in Tasmania into modern times (Figure 2). Indeed Sahul, like the Americas, also had no earlier hominins. This is despite the recent Indonesian discoveries of *Homo erectus* and their 'Hobbit' descendents, *H. floresiensis*, living between 800 000 and 12 000 ya just 100 km from Sahul's coastline (Morwood et al., 2004). As yet, there is no convincing evidence that premodern humans had colonized Sahul (O'Connell and Allen, 2004). The people that entered the continent were behaviorally modern humans.

Paleoenvironments

Research on the past climate of Sahul (Pleistocene New Guinea–Australia–Tasmania) has identified major changes in sea levels and terrestrial environments. These have had a significant influence on the ecological structure of this continent, affecting the distribution of potential food and the ability of humans to make a living off the land, especially around the coasts, mountains, and arid interior. Human responses were not uniform however and different behavioral patterns are documented in archaeological sites from different regions. These climatic changes were driven by large-scale Milankovitch Cycles that changed the distribution of incoming solar radiation permitting the buildup of ice at the poles. Vast amounts of water were frozen and locked up as glaciers, reducing the sea levels by at least 100 m across the globe. Research on deep-sea cores and uplifted coal terraces on the Huon Peninsula, Papua New Guinea, suggest that sea levels have fluctuated over the last 100 000 years or more. The last glacial cycle began about 130 000 ya with a series of sea-level rises and falls trending toward lower levels until about 18 000 ya after which the sea rose, stabilizing about 6000 years BP (Lambeck and Chappell, 2001).

Previously, it had been thought that the last glacial was a spike of much colder temperatures and lower precipitation between 20 000 and 18 000 ya. New data suggest that it was more active over a longer period with increased magnitude and frequency from about 30 000 ya (Lambeck et al., 2002). The climatic cycles appear to have oscillated rapidly approaching the Last Glacial Maximum (LGM). These changes would have had implications for humans over the medium term with influences on the distribution of prey animals and plant foods. More significantly for people, embedded within these large environmental fluctuations were smaller, more dramatic El Niño–Southern Oscillation (ENSO) events that began at least 45 000 ya (Kershaw et al., 2003). During this period there was an increase in fire-tolerant vegetation and a steady decline in precipitation that in turn increased periods of dust circulation blowing west out over the Indian Ocean and east into the

Figure 1 Selected late Pleistocene sites from New Guinea, Australia, and Tasmania. During this time the continent expanded to over 11.5 million square kilometers when sea levels dropped to 130 m below present day levels.

Tasman Sea (Hesse and McTainsh, 2003; Shulmeister et al., 2004). Although some researchers have suggested wind speeds were at least 8 km/hour greater during the LGM than present day, dust particle analysis would indicate that it was more arid than windier.

Terrestrial evidence from the Willandra Lakes system in southeastern Australia suggests alternating wet and dry periods recorded in the lakeside lunettes as sand and clay layers, respectively (Bowler, 1998). These support evidence

from the marine chronology for moister conditions before 43 000 years BP when the lake system was full. A sharp but short-lived decline in water levels was recorded around 40 000 years BP. It is at this time that Australia's oldest human remains were recorded, Mungo 3. From this period the lake levels fluctuated with less severe conditions represented by alternating clay and gravel deposits. Freshwater shell midden and aquatic fauna are abundant in human sites around the lakes at this time. Fishing with gill nets has been

argued based on the remains of fish otoliths in the middens. After 16 000 years BP there was a steady decline in human occupation as the lakes dried up completely.

In the tropical north, pollen cores from Lynch's Crater on the Atherton Tableland have provided detailed sediment records back to at least 130 000 years BP (Kershaw, 1994; Figure 3).

From then until about 78 000 years BP rainforest angiosperms were dominant with some minor dry sclerophyll woodland species. Increasing amounts of *Eucalyptus* pollen, particularly around 35 000 years BP indicates further drying in northern Australia concomitant with changes in southern Australia. Increases in charcoal around 45 000 years BP have been argued to represent human occupation of the Tableland (Turney et al., 2001) although recent archaeological

Figure 2 The Tasmanian Devil (*Sarcophilus harrisi*) remains Australia's sole marsupial carnivore. Unlike *Thylacinus cynocephalus* and *Thylacoleo carnifex* it is primarily a scavenger (photograph by R. Cosgrove).

Figure 3 Lynch's Crater on the Atherton Tablelands, north Queensland has a pollen record stretching back at least 130 000 years. The extinct volcano contains a long continuous record of peat accumulation which records the change from rainforest to fire-adapted species like *Eucalyptus* around 30 000 years BP until 8000 years BP when rainforest again invaded the landscape (photograph by R. Cosgrove).

research suggests the earliest dates for humans here is around 7500 years BP (Cosgrove, 2005). A major period of glacial advance and global cooling after 30 000 years BP saw sclerophyll vegetation become dominant on the Atherton Tablelands, all but replacing rainforest species (Kershaw, 1994). Some tropical rainforest refugia remained that sustained endemic species like the tree kangaroo and cassowary into the Holocene. It was only after 8000 years BP that rainforests began to expand again after increases in rainfall during the climatic optimum.

The arid center of Australia gradually become drier, particularly after about 20 000 years BP with increased dust and lower temperatures enhanced by reduced vegetation cover and a trend towards grass species (Field et al., 2003; Hesse and McTainsh, 2003; Pack et al., 2003). At this time, the complete drying of lake systems around the arid margins by 16 000 years BP led to reactivation of dune and lunette building activity (Bowler, 1998). Other environmental changes to Australia's Pleistocene ecosystems have been said to be a direct result of human firing regimes (Miller et al., 2005) which led to the extinction of *Genyornis newtonii*, a large flightless bird in central Australia 50 000 years BP. Results from other studies on the edge of the arid zone show this bird co-existed with humans until at least 30 000 years BP (Trueman et al., 2005).

New Guinea and Tasmania were finally cut off from Australia by rising seas toward the end of the LGM around 9000 and 14 000 years BP, respectively.

Chronology of Human Arrivals

There has been continuing debate about the timing of human entry into Australia. Several challenges have confronted archaeologists when addressing this question. The first and most contentious is the accuracy of the range of dating techniques, the dynamics of site formation processes, and taphonomy. The protagonists fall into two main groups; those advocating settlement 40 000–45 000 years BP and those arguing for occupation before 60 000 years BP. There have been claims of occupation before 100 000 years BP but so far direct archaeological evidence for this has been lacking.

Much of the debate hinges on demonstrating the clear and unequivocal relationships between dates, artifacts, and sediments (O'Connell and Allen, 1998, 2004). Because the timing of human occupation intersects with the present known limits of radiocarbon, it has been necessary for geochronologists to refine dating methods and to understand archaeologists' concerns regarding site-formation processes. Developments in accelerator mass spectroscopy (AMS) and luminescence dating have provided a better chronological framework to the problem but have exposed weaknesses in the application of the results to archaeological records. Concerns have been raised about the taphonomic effects of termites, contamination by older sediments of younger archaeological deposits, movement of stone tools within sandy deposits, and the inadequate bleaching of the quartz grains to reset the luminescence clock (Figure 4).

O'Connell and Allen (2004) list eight sites that they argue have unequivocal archaeological evidence for earliest human occupation between 40 000 and 45 000 years BP.

Geographically these sites are located across the continent, from the northern tropics (e.g., Riwi, Huon Peninsula, and Carpenter's Gap), to the temperate southern and arid regions of Devils Lair, Allen's Cave and Lake Mungo. More controversial is the claim for artifacts in the oldest Lower Mungo sedimentary unit dated to about 50 000 ya (Bowler, 1998). Other researchers remain unconvinced since no refitting of artifacts from this level has been undertaken (O'Connell and Allen, 2004). In higher levels, stone flakes have been displaced from their cores by up to 60 cm, implying similar mechanisms for reworking the sediments and their contents in the lower layers. If the post-50 000 years BP chronological patterns hold, it suggests that a wide variety of environments were settled relatively swiftly, within 5000 years of initial landfall. O'Connell and Allen dismiss the two sites claimed to be 50 000 years BP of Malakunanja and Nauwalabila as having unconvincing associations of stratigraphy, chronology, and artifacts (Figure 5).

By the time the dry Bass Plain had been exposed (40 000 years BP), people took the opportunity to cross into what was then the toe of Sahul, now Tasmania. Here evidence based on radiocarbon chronology suggests Tasmania was first settled 35 000 years BP. The two earliest dates come from Warreen Cave and Parmerpar Meethaner in the southwest and north of Tasmania, respectively (Cosgrove, 1999; Figures 6 and 7).

In Melanesia, humans had settled in the Bismarck Archipelago and the Solomon Islands by at least 40 000 ya at Buang Marabek and 29 000 ya at Kilu (Leavesley et al., 2002). By 20 000 ya people were using boats to move possums and obsidian across water gaps as a means of subsistence and technological adaptations to new lands (Allen et al., 1989). There is also data to show humans had begun utilizing tropical rainforest on New Britain at the open site of Yombon by 35 000 years BP (Pavildes, 2004). The spread and relative speed of settlement across Sahul suggests that environmental

barriers did not restrain early modern human movement. They appear to have taken the opportunities to expand their range and adapt to the many and varied ecosystems of the Sahul land mass. These achievements point to an established social and economic system, probably already in place before they crossed the sea separating Southeast Asia and Sahul (Figures 8 and 9).

Physical Anthropology

Much of what we know about the physical anthropology of the earliest Australians has come from southeast Australia.

Figure 5 The site of Nauwalabila is claimed to be at least 50 000 years old (photograph by J. Allen).

Figure 4 Dating the earliest human arrivals in Sahul has been contentious. Recent use of optically stimulated luminescence (OSL) techniques has pushed back the ages to between 45 000 and 55 000 ya. Problems arise through contamination and the inadequate resetting of the luminescence clock. Termite activity can be a source of this because they continually circulate sand grains above and below ground. A large termite mound is located within the overhang of this rock shelter and when it collapses may contribute to this problem (photograph by J. Allen).

Figure 6 Parmerpar Meethaner is one of the oldest Tasmanian sites dating back to at least 34 000 years BP. It is located in the Forth River valley in northern Tasmania (photograph by R. Cosgrove).

Kow Swamp and Lake Mungo have provided much of this evidence although there are widely differing interpretations of these human fossil remains. The debate largely stems from the two competing models of the origin and global spread of humans known as the Out-of-Africa and Regional Continuity (Mulvaney and Kamminga, 1999). The former asserts that anatomically and behaviorally modern humans moved out of Africa perhaps 100 000 ya replacing an earlier migration of hominid forms represented by robust *H. erectus* and *H. ergaster*

Figure 7 The archaeological section of Parmerpar Meethaner reveals a series of layers containing stone artifacts, bone, and charcoal. The upper 30 cm is Holocene dating to between 3500 years BP and modern times. From the middle section to the base of the trench ages range from 18 000 to 34 000 years BP. A date of 40 000 years BP in the lowest section does not contain any human artifacts (photograph by R. Cosgrove).

Figure 8 Matemkupkum on New Ireland dates back at least 35 000 years. It contains the oldest evidence of sea fishing anywhere in the world (photograph by R. Frank).

that settled in Eurasia and Southeast Asia. Some archaeologists question the chronology although arguments have been mounted to show anatomically modern humans did not establish beyond the Levant after reaching there 70 000 years BP. It is only after 45 000 years BP that there is unequivocal data to show behaviorally modern humans reaching Southeast Asia and Sahul. Others propose an earlier movement of modern humans out of Africa earlier, around 70 000 years BP along the southern coasts of Eurasia into Southeast Asia, and then perhaps into Sahul. However there is no reliable archaeological evidence to suggest a human landfall of this antiquity apart from problematic dating of the Mungo 3 skeleton at around 60 000 years BP (Bowler and Magee, 2000; Gillespie and Roberts, 2000; Thorne and Curnoe, 2000; Figure 10).

Put simply, the Regional Continuity model proposes that there was only one migration out of Africa by *H. erectus/ergaster* over 1 million ya whose ancestors evolved *in situ* into regional populations of later modern humans. Physical anthropologists who argue for this model stress change through time from robust to gracile morphology through gene flow between geographically separate populations. However, significant gaps in the fossil record and the appearance of similar cranial morphologies on different continents 10 000 km apart continue to hamper the testing of this model (Stringer, 2002). In addition, the new finds from Flores and their late dates suggest that *H. erectus* did not evolve into later modern humans but remained a separate species until only 12 000 ya in the form of *H. floresiensis* (Morwood et al., 2004). Its discovery on the

Figure 9 Yombon has a series of volcanic ash layers seen here as alternating dark and light bands. Dr Christina Pavlides indicates the lowest late Pleistocene layer dated to 35 570 years BP. Over 20 chert stone tools were found here. The raw material for these artifacts was quarried locally while the obsidian found in the layers above was imported from the other side of the island (photograph by C. Pavlides).

island of Flores poses more questions than answers and reflects the complex nature of the human evolutionary process.

The Continuity Model asserts that the earliest Australian arrivals were essentially robust, represented by the incomplete WLH50 skull from the Willandra Lakes, although others argue that its form is the result of pathology, large size, or deformation. The model posits two waves of migration into Australia; an early one represented by WLH50 from Java and a later one represented by more gracile morphology from China. The proponents argue that the present day Aboriginal populations are the result of a mixture of the robust and gracile groups during the Holocene. A second competing view sees the presence of the two morphologies as the result of skeletal variations and sexual dimorphism within a single population. It has also been argued that cultural isolation and artificial head binding also influenced the morphological characteristics found in the Kow Swamp population (Brown, 2005; Pardoe, 1995).

Both models imply an increasing gracilization over time, where robust forms are followed by gracile skeletal morphology, particularly of the skull. The interesting aspect of the Australian data is that the earliest skeletal remains at Lake Mungo are gracile. These date to around 40 000–45 000 years BP. Mungo 3 and Mungo 1 contrast with the robust remains from Kow Swamp, Cohuna, and the Willandra Lakes hominid WLH50. These latter specimens are all dated younger than 20 000 years BP, and in the case of the best preserved at Kow Swamp, date only between 13 000 and 9500 years BP. That the Mungo fossils predate the robust group by a considerable time implies a significant degree of diversity and variation in Aboriginal populations in Sahul. The evidence does not support the notion of separate ancestral lineages (Stringer, 2002). It suggests a more complex situation involving multiple waves of people entering Sahul, affected morphologically by the combined effects of a harsh glacial climatic, generally low population numbers, and cultural and/or geographic isolation. Only one thing is clear, that the samples are small and represent individuals rather than populations. The study of a more representative sample of pre-Holocene skeletal remains will bring a better understanding of the past population dynamics of Sahul.

Figure 10 Lake Mungo and the Walls of China. Here severe gully erosion can have a profound influence on the location of artifacts and bones. Although human settlement is well dated to about 45 000 years BP, there is still some disquiet about the integrity of some of the lowest artifacts found below the burial site of the Mungo 3 skeleton (photograph J. Allen).

Impacts of Humans on Environments

Two issues dominate the debates on human influences on past environments, the extinction of Sahul's megafauna and the effect of fire on the biota (Bowman, 1998; Field, 2004; Roberts et al., 2001; Wroe et al., 2004). More than 50 species of animals became extinct during the late Pleistocene, and while many weighed less than 40 kg, a significant proportion weighed over 100 kg. The most well-known include *Diprotodon*, *Sthenurus*, and the large flightless bird, *Genyornis*. Arguments over the causes and timing of their extinction have been intense. The explanations include the over-kill hypothesis or 'blitzkrieg' whereby humans, shortly upon arrival, hunted these large beasts to extinction, climatic effects of increasing aridity, ecosystem modification, or a combination of climate and human hunting (Figures 11 and 12).

Figure 11 The skull of a *Diprotodon optatum*. Note the large upper and lower incisors as well as the bony structure on top of the maxilla thought to be for the attachment of powerful muscles. These large herbivores weighed more than 1000 kg. They were probably browsers preferring the open, arid lands, using their sharp incisors to crop hard-stemmed vegetation (photograph by R. Cosgrove).

Figure 12 The postcranial skeleton of *Diprotodon* suggests a very heavily built animal with long proximal and short distal limbs. The feet were relatively small and probably had heavy padding (photograph by R. Cosgrove).

Evidence for the swift demise of megafauna due to over-hunting has come from systematic dating of sediments using luminescence techniques. Age estimates on some 12 taxa suggest extinction between 40 000 and 50 000 ya. The dates come from sediments associated with articulated megafauna bones, not from archaeological sites. The results have been questioned by a number of researchers who are critical of the selection of naturally deposited semi-articulated skeletons. They argue that to truly understand the mechanism and age of the extinctions, human sites associated with megafauna must be studied (Wroe et al., 2004).

Other geochronologists have dated eggshell from the extinct *Genyornis* and extant emu (*Dromaius*) and found isotope variation in the two species from about 140 000 ya (Miller et al., 2005). Their work included the analysis of thousands of eggshell pieces of each species from central Australia. They argue that *Genyornis* became extinct about 45 000 years BP under a regime of altered ecological conditions as shown in the changed isotope values beginning about 50 000 years BP. They dismiss climate as a cause and propose human alternation to natural vegetation patterns by fire as an explanation. Drought adapted vegetation, including fertile grasses, gave way to fire adapted desert scrub. Because isotope values in the eggshell demonstrate *Genyornis* was apparently restricted to a narrow range of grasses, it is suggested that it could not adapt to the fire-prone desert vegetation and died out. Other workers reject the stated impact of Aboriginal firing on the Pleistocene landscape, arguing that it has been overemphasized (Bowman, 1998). They see the relationship between past Aboriginal firing practices and the resultant landscape as a highly complex ecological interaction. To understand it requires an apposite temporal resolution of the ecological and archaeological record.

Other data contradict the view that there was widespread extinction of *Genyornis* by 50 000 years BP (Trueman et al., 2005). Evidence from the archaeological site of Cuddie Springs suggests that *Genyornis* survived for another 15 000 years in co-existence with humans. In addition, the site contains thousands of megafaunal bones in layers below the lowest stone tools showing a diminishing species diversity in the absence of humans through time. The implication is that megafauna may have already been in decline due to sustained long-term landscape changes driven by climatic factors (Figures 13 and 14).

The most common species at Cuddie Springs are *Diprotodon optatum* and *Genyornis newtonii* and these are clearly associated with artifacts sandwiched between two hardened pavements dated to between 30 000 and 35 000 years BP (Field, 2004). The most parsimonious explanation for the data is that these species retreated to the better-watered edges of the expanding arid zone, leaving the less specialized emus to survive in the drier interior where they live at present day. *Genyornis*'s prolonged co-existence with humans at Cuddie Springs can be explained this way without recourse to the overdramatization of the human-caused extinction theory. Nevertheless they appear to have finally succumbed to a drying continent and human predation (Figures 15 and 16).

Ultimately the question of megafauna extinction and human influence is undeniably linked to a determination of the arrival time of people on the Sahul continent. Until this is resolved the cause of extinctions remains problematic. In Tasmania there is a reasonably good understanding of the

Figure 13 Cuddie Springs is situated in the centre of a shallow depression. Many thousands of megafauna bones have been excavated in association with artifacts (photograph by R. Cosgrove).

Figure 14 Excavation at Cuddies Springs revealed the long bones of *Genyornis* lying next to stone implements (arrowed). The lowest human occupation is dated to 35 000 years BP (photograph by R. Cosgrove).

Figure 15 An artistic impression of *Diprotodon optatum*. It probably stood about 1.8 m at the shoulder and had an overall length of 3.4 m (illustration A. Musser and Australian Museum).

human's entry time of about 35 000 years BP. Although megafauna were present in Tasmania, none have been recorded in over 600 000 bones excavated from seven late Pleistocene human cave sites (Cosgrove and Allen, 2001). All are extant animal species. It strongly suggests that megafauna were already locally extinct before humans arrived (Figures 17 and 18).

Figure 16 *Genyornis newtonii* is a distant relative of the emu but was larger. It stood over 2 m and had large robust feet (illustration A. Musser and Australian Museum).

Figure 17 Bone Cave in southwest Tasmania has human occupation extending back at least 29 000 years. It contains two main occupation periods; from 29 000 years BP to about 23 000 years BP then a hiatus until 16 000 years BP when occupation intensified (photograph by R. Cosgrove).

Continent-wide explanations are therefore unlikely to address this issue in the short term. The expectation is that these will be much more complex and focused at local or regional scales. Additional work needs to be done in identifying causal mechanisms and the effects. Ecological modeling and the identification of other archaeological sites to establish regional variability may go some way in solving this vexatious question.

Figure 18 Southwest Tasmanian sites are characterized by there extreme richness of stone tools and bones. It is not uncommon to find 250 000 bones and 35 000 stone tools in less than a cubic meter of deposit (photograph by R. Cosgrove).

Technology and Economy

late Pleistocene Sahul stone technology has been characterized as conservative and for the most part unchanging. In the past, these notions have been used to portray the early colonists as technologically backward, without regional variability. Recent advances in fieldwork, method, and theory have largely debunked this view, recognizing much more behavioral variability across Sahul. It is clear that the first settlers must have had reliable sea-going rafts or canoes. A level of organizational capacity and language must have also been present to carry out these voyages. Obviously the organic material necessary for the construction of these boats has long since decayed although sea faring continued throughout the Bismarck Archipelago during the late Pleistocene as demonstrated by the presence of traceable stone artifact raw material. Significant quantities of obsidian have been recorded in the late Pleistocene sites on New Britain and New Ireland for example. Recent research at Kupona na Dari indicates that it was used soon after human arrival about 40 000 years BP (Torrence et al., 2004). Obsidian was transported by boat up to 32 km and in the case of sites on New Ireland at Matenbek, up to 300 km from sources at Mopir and Talasea by 20 000 ya (Figure 19).

Coupled with this movement is evidence for the economic structuring by human colonizers. It has been argued that the early settlers to the Bismarks were highly mobile, utilizing resource patches, cleared with 'waisted' axes and fire as a means of breaking the tropical canopy. Before 20 000 years BP water crossings were made into previously uninhabited areas where resource levels and interior geography were unknown. Significant marine distances were crossed where the next landfall could not be seen before leaving their origin point, as was the case of Kilu, Solomon Islands 29 000 years BP. Exploration included a degree of deliberate voyaging to locate stone quarries that meant groups were mobile, exploiting a wide range of resources from both the coast and inland. After 20 000 years BP there were transfers of animals as a risk-reducing device, raw materials, and increased sailing to more remote islands.

The earliest and most typologically distinct tools are ground-edge axes that have been found across northern Australia and New Guinea. They only appear in the archaeological record in southern Australia after 5000 years BP. 'Waisted' and ground-edge hatchets are dated to over 40 000 years on the Huon Peninsula and 26 000 years at the New Guinea highlands site of Kosipe. Ground-edge hatchets were recovered from the sites of Malangangerr and Nawamoyin in the Northern Territory that date to 23 000 years BP. Archaeologists have suggested that the typological links indicate a degree of cultural connectedness and perhaps a common origin of human groups operating at this time. They were probably used in forest clearance to create small, disturbed forest patches to encourage useful and productive plant foods (Figures 20 and 21).

Although typological schemes have been put forward in the past to describe the flaked stone technology of Sahul, several objections have been raised that counter the usefulness of typological groupings (Hiscock and Attenbrow, 2003). Indeed with

Figure 19 Small obsidian artifacts found in the sites on New Ireland. These implements have been worked down to a small size, indicative of raw-material rationing (photograph by R. Frank).

Figure 20 This 23 000-year-old ground-edge hatchet was found at the northern Australian site of Malangangerr. They are made from porphyritic dolerite. It is one of the oldest such implements in the world (photograph by J. Allen).

the recent discovery of microliths dated to 15 000 years BP at GRE 8 and Walkunder Arch in Queensland aged 13 000 years BP, their usefulness as chronological markers of mid-Holocene technological change is no longer viable (Figure 22).

The appearance of grindstones perhaps 30 000 years BP also suggests that early tools for seed-grinding exploitation were instrumental in opening up opportunities for the settlement of challenging environments such as deserts. The use of organic technology has also been recorded at Wylie Swamp where barbed spears and boomerangs dated to at least 10 000 years

Figure 21 Two main phases of occupation were found at Malangangerr; an early Pleistocene and a later Estuarine phase containing shell midden and smaller-sized artifacts (photograph by J. Allen).

Figure 22 Walkunder Arch is a large limestone cave that contains a series of fine soil lenses dating to the Holocene period. In the darker reddish layers small backed microliths were recovered indicating that these implements have a late Pleistocene origin (photograph by R. Cosgrove).

Figure 23 Bennett's wallaby is the most common prey animal in the Tasmanian Ice Age sites. Studies of the annuli in their teeth show that the majority were hunted during the autumn and late spring, with many killed during winter. This was the harshest time of the year but people were able to use the valleys in a planned and systematic manner that indicates organization skill and forward planning (photograph by R. Cosgrove).

BP have been preserved. In Tasmania and southwest Western Australia bone points dating back 30 000 years BP have been identified. These were probably used as awls, needles, and spear points (Mulvaney and Kamminga, 1999). Given these developments the classification of the late Pleistocene stone technology under the rubric, Core Tool and Scraper Tradition is now considered redundant.

In Tasmania, humans were exploiting wallabies as the major prey animals. Hunters used sites in the valleys primarily between autumn and early spring, capturing the macropods for their fat, fur, and sinews. Body-part analysis of the butchered carcasses suggests selection of the lower limb bones processed for marrow. The pattern of exploitation suggests optimal foraging of Bennett's wallaby. They were an excellent prey choice as they took little effort to obtain, energy returns were higher for the effort spent in their search, and killing and processing took place in the patches of grassland on which they fed (Cosgrove and Pike-Tay, 2004; Figure 23).

Global Expansion 300 000–8000 Years Ago, Americas

T Goebel, Texas A&M University, College Station, TX, USA

Introduction

The peopling of the Americas during the Late Quaternary was one of the most significant events in the history of our species. It initially required adaptation to the far north (Hoffecker, 2005), then further adaptation to a series of new environments – littoral zones, inland deserts, woodlands and grasslands, high mountains, tropical forests, even Sub-Antarctic islands in the Horn of South America (Dillehay, 2000). The earliest Americans made first contact with a variety of plant and animal species, and these surely had a hand at shaping their technology, subsistence, settlement, and ideology. In North America, the first Americans dispersing from the north found familiar large-bodied prey species, for example, mammoth, bison, horse, and a variety of cervids, but as they dispersed further into Mesoamerica and South America, they encountered alien plants and animals, requiring significant foraging and technological adjustments. Dispersal may have begun as early as 30 000 calendar years ago (ka), but more likely the process unfolded during the Late Glacial, closer to 16–13 ka. By 12 ka, modern humans occupied virtually all of ice-free America.

Study of the origins and dispersal of the first Americans is an interdisciplinary endeavor. Archaeologists, biological anthropologists, geneticists, geoscientists, and paleoecologists work together to disclose who the first Americans were, where and when dispersal began, the routes taken and environments encountered, and processes of exploration and settling of new lands. Human colonization of North and South America certainly had a significant impact on plant and animal communities, but equally important were effects of climate change on dispersing Americans. Dispersal occurred amidst significant global climate change – the transition from the last glacial to the present interglacial period.

Old World Origins

From where did the first Americans come? There are two possibilities – from northeast Asia via the Bering Land Bridge or southwest Europe via the North Atlantic Ocean (Figure 1). Current genetic evidence overwhelmingly supports the Beringian model. All contemporary Native American lineages, or haplotypes, of mitochondrial (mt)DNA and the non-recombining portion of the Y chromosome share common ancestors with southern Siberians, not Europeans (Derenko et al., 2001; Karafet et al., 2006; Merriwether, 2006; Perego et al., 2010; Schurr and Sherry, 2004; Starikovskaya et al., 2005; Zegura et al., 2004). Further, segments of ancient DNA amplified from prehistoric Native American remains so far have been attributed only to haplogroups or haplotypes of Asian origin (Gilbert et al., 2008; Kaestle and Smith, 2001; Kemp et al., 2007; Malhi et al., 2007; Perez et al., 2009; Raff et al.,

2011; Smith et al., 2005). Some of these remains are quite ancient: the human coprolites from Paisley Caves (Oregon) date to ~14.9–13.9 ka, while human bone from On Your Knees Cave (southeast Alaska), Wizards Beach (Nevada), and Arroyo Seco 2 (Argentina) date to 10.5–10.2, 10.6–10.2, and 8.8–7 ka, respectively (Figure 1).

Corroborating evidence supporting an Asian origin of the first Americans comes from recent comparative analyses of the First Americans themselves. Skulls from Spirit Cave (Nevada), Kennewick (Washington), Lagoa Santa (Brazil), and other 'Paleo-American' sites bear strong similarities with modern Ainu and prehistoric Jomon populations of Japan as well as southeast Asian populations in general (Brace et al., 2001; Chatters, 2000; González-José et al., 2005; Lahr, 1995; Neves and Hubbe, 2005; Neves et al., 2004, 2007b; Powell and Neves, 1999; Steele and Powell, 2002). All these groups are likely related through some ancient source population that existed across Asia during the late Pleistocene, one that will become better characterized as the sample of Asian Paleolithic specimens increases. Archaeologically, greater northeast Asia (including eastern Russia, Mongolia, north China, Korea, and Japan) is known to have a rich record of Upper Paleolithic sites and complexes; continued research there will ultimately lead to a precise record of Native American origins.

Why, then, do some scientists continue to argue that the first Americans came from Europe? The reasons for this are based on archaeological observations made by proponents of the Iberian model (Bradley and Stanford, 2004). Based on particular similarities in the lithic industries of late Pleistocene European and North American complexes, they argue that prior to 19 ka Upper Paleolithic Iberians of the Solutrean culture carried bifacial and blade technologies in boats across the North Atlantic Ocean to eastern North America. These populations persisted there in sufficient numbers to create a minimal pre-Clovis record, and around 13 ka, they developed bifacial fluting technology that spread geographically across North America by either migration or diffusion among existing populations. Countering the Solutrean origins model are the arguments of Straus et al. (2005) that (1) technological similarities between Solutrean and Clovis are more likely due to evolutionary convergence, not phylogenetic relationship; (2) Solutrean foragers rarely exploited maritime resources, and there is no evidence for Solutrean seafaring technology; (3) the evidence for pre-Clovis in the eastern United States is unconfirmed; and (4) the temporal gap between the youngest Solutrean and oldest Clovis sites is too wide to provide a credible link. Given the current genetic record, the most parsimonious explanation for the origins of the first Americans is the traditional Beringian model.

Determining when humans first dispersed into Beringia and subsequently the Americas is less clear. Two benchmark events, however, anchor the beginning and ending points of this process, one in Asia and the other in North America. First,

Figure 1 Early archaeological and human paleontological sites mentioned in text (1, Tianyuan; 2, Pokrovka; 3, Yana; 4, Berelekh; 5, Ushki; 6, Tuluaq; 7, Nenana complex sites (Walker Road, Moose Creek, Dry Creek, Owl Ridge); 8, Tanana valley sites (Upward Sun, Swan Point, Broken Mammoth); 9, Bluefish Caves; 10, On Your Knees Cave; 11, Manis; 12, Ayer Pond; 13, East Wenatchee; 14, Kennewick; 15, Paulina Lake; 16, Paisley; 17, Wizards Beach; 18, Spirit Cave; 19, Channel Island sites (Arlington Springs, Cardwell Bluffs, CA-SRI-512); 20, San Pedro valley sites (Lehner, Murray Springs); 21, Simon; 22, Buhl; 23, Bonneville Estates Rockshelter; 24, Anzick; 25, Colby; 26, Mountaineer; 27, Barger Gulch; 28, Arch Lake; 29, La Sena; 30, Lovewell; 31, Buttermilk Creek sites (Friedkin, Gault); 32, Kenosha County sites (Schaefer, Hebior, Mud Lake); 33, Meadowcroft; 34, Shawnee-Minisink; 35, Miles Point; 36, Cactus Hill; 37, Topper; 38, Page-Ladson; 39, Quintana Roo enclaves; 40, Peñon; 41, Pedra Pintada; 42, Pedra Furada; 43, Lagoa Santa; 44, Quebrada Jaguay; 45, Quebrada Santa Julia; 46, Monte Verde; 47, Agua de la Cueva; 48, Arroyo Seco 2; 49, Pasa Otero 5; 50, Piedra Museo).

human paleontological remains from northeast Asia, including the nearly complete modern human skeleton from Tianyuan Cave, China (directly dated to 42–39 ka) (Shang and Trinkaus, 2010) and the front of a modern human calotte from Pokrovka, Siberia (directly dated to 32.5–31.5 ka) (Akimova et al., 2010) together indicate that modern *Homo sapiens* ultimately dispersing from Africa had arrived in the region 40–30 ka. This is corroborated by genetic coalescence estimates for the mtDNA haplotypes of contemporary northeast Asians (Comas et al., 2004; Forster, 2004), as well as radiocarbon estimates for the emergence of Upper Paleolithic technologies in southern Siberia (Goebel, 1999). The second benchmark even relates to the appearance of Clovis, the earliest unequivocal complex of archaeological sites known in the Americas. Bifacial projectile points with distinctive flutes, or grooves, at their bases, blade tools detached from prismatic blade cores, and carefully carved ivory and bone tools characterize Clovis and have been documented across most of temperate North America 13.3–12.8 ka (Walters and Stafford, 2007). These two events – appearance of the first modern humans in northeast Asia and emergence of the Clovis complex in North America – provide lower- and upper-limiting dates for dispersal to the Americas: 40 and 13.3 ka.

Paleoenvironments and Routes of Dispersal

The ‘empty’ environments of late Pleistocene America were highly variable geographically and temporally and created numerous opportunities and challenges for human settlers.

The first challenge was entering the hemisphere. The human genetic evidence discussed above suggests the entry point was the Bering Land Bridge, which connected northeast Siberia and Alaska during glacial periods of the Pleistocene. During the late Pleistocene between about 30 and 20 ka, the land bridge reached its greatest extent in recent history, spanning nearly 1000 km from north to south (Figure 1; Brigham-Grette et al., 2004). Late-glacial melting of the world’s glaciers and ice sheets caused rising sea levels and gradual flooding of the land bridge, in turn leading to a shrinking terrestrial landscape and an ever-changing sea margin (Elias et al., 1996, 1997; Manley, 2002). Current estimates on final flooding of the land bridge suggest this event occurred around 13–12.5 ka (Brigham-Grette et al., 2004; Elias et al., 1996). The land bridge itself remained relatively ice-free through most of the last glacial (Glushkova, 2001; Kaufman and Manley, 2004), and full-glacial vegetation communities in Beringia are generally thought to have been open tundra-steppes reflecting cold, dry climate. Local conditions, however, were variable, with steppe-tundra occurring in inland areas of eastern Beringia (interior Alaska and northern Yukon) and more mesic tundra dominating lowlands of the land bridge itself (the now submerged shelves of the Bering and Chukchi seas) (Bigelow et al., 2003; Elias and Crocker, 2008; Kuzmina et al., 2008). Large mammal fauna characterized the land bridge – mammoth, bison, horse, reindeer, and musk ox during full-glacial times (e.g., Lorenzen et al., 2011), with additions of wapiti and moose during the Late Glacial (Guthrie, 2003). The land bridge connecting Asia and America, therefore, offered opportunities for settlement throughout the late Pleistocene.

Canada during the late Pleistocene was covered by widespread glacial ice sheets. These would have formed a

significant barrier for human dispersal during most of the last glacial cycle; however, during deglaciation, ‘ice-free corridors’ opened first, leading to plant and animal dispersals from the north and south into recently deglaciated landscapes. Two corridors emerged, one along the Pacific Ocean coast and the other along the eastern flank of the Canadian Rocky Mountains (Figure 1; Clague et al., 2004; Dyke, 2004). The coastal corridor may have opened first, by 16–15 ka (Mandryk et al., 2001); however, luminescence dates on wind-blown sands in central Alberta indicate an ice-free interior corridor by about the same time (Munyikwa et al., 2011), nearly 2000 years earlier than previously thought. Confirmation on the timing of the opening of the corridors eventually may come from direct dating and DNA analysis of dispersing bison and other megafauna (e.g., Shapiro et al., 2004; Zazula et al., 2009). The current data suggest that although Beringia was cut off from the rest of the Americas during the Last Glacial Maximum (LGM), by 15 ka two south-bound avenues of dispersal may have been available for humans.

In temperate North America during the height of the last glacial, the Cordilleran ice sheet expanded southward into northern Montana and Washington, and the Laurentide ice sheet spread deep into the American Midwest and Mid-Atlantic states (Dyke, 2004). Ice-sheet recession during the Late Glacial was gradual and at times stalled or even reversed. The northern United States, though, became completely ice-free by about 13 ka, while in northeastern Canada, deglaciation was not complete until well into the Holocene. Mountain glaciers south of Canada expanded and receded during the late Pleistocene as well, reaching their greatest extent around the LGM (Gillespie and Zehfuss, 2004; Pierce, 2003). Late-glacial humans entering temperate western North America encountered relatively cool and wet climates and richer environments than exist there now. Large pluvial lakes filled many valleys of today’s Great Basin, Sonoran, and Chihuahuan deserts (Ballenger et al., 2011; Goebel et al., 2011; Metcalfe et al., 2002), and open woodlands would have been common there as well as in the Great Plains beyond the Rocky Mountains. East of the Mississippi River, coniferous forests dominated landscapes as far south as Tennessee and the Carolinas, and mixed hardwood forests existed in the deep south (Delcourt and Delcourt, 1987; Williams et al., 2004). These conditions gradually changed during the early postglacial period, leading to significant drying in the west and northward displacement of boreal communities in the east. Extinctions of mammoth, mastodon, horse, and other large mammals occurred during this time, some before the Clovis era and others synchronous with it (Grayson and Meltzer, 2002).

In Central and South America, first colonizers encountered environmental conditions that were generally cool and dry, compared to today (Markgraf, 1989; Munyikwa, 2005; Tripaldi et al., 2011). In Central America, forests still likely covered lowland areas (Ranere, 2006). The Panamanian isthmus was not significantly broader during the Late Glacial than it is today; it certainly would have been a ‘bottleneck’ for dispersing human populations. In South America, environmental records in the Andes Mountains chronicle a glacial advance coincident with the LGM in the northern hemisphere, ca. 20–18 ka, but some records also point to a secondary advance during the Late Glacial, 17–14 ka, with deglaciation occurring by 12.5 ka

(Coronato et al., 2004; Harrison, 2004; Hastenrath, 2009; Helmens, 2004; Mark et al., 2005). From the central Mexican highlands to the southern Andes, snow line during the LGM appears to have dropped as much as 1400 m from today, implying maximum summer temperatures as much as 8 °C cooler than now (Harrison, 2004; Helmens, 2004; Kühle, 2004; Mark et al., 2005). Vegetation communities in Mexico were generally characterized by extensive grasslands and open mixed forests (Lozano-García et al., 2005), while in South America, they varied temporally, with open grasslands or dry shrublands during the height of the last glacial, followed by the development of forests during the Late Glacial, as early as 17 ka locally (Burbridge et al., 2004; Hessler et al., 2010; Hodel et al., 2008). In some areas, for example the Peruvian Puna and Argentinian Pampas, open treeless landscapes persisted into the Holocene, despite relatively humid conditions ~14–12 ka (Aldenderfer, 1999; Quattrocchio et al., 2008). Highland Peru, the northern Bolivian Altiplano, and southern Chile, however, appear to have been wetter during the late Pleistocene than today, with Chilean landscapes being characterized by ‘hyperhumid’ forests (Chepstow-Lusty et al., 2005; Hillyer et al., 2009; Kaiser et al., 2008). Southeast Brazil, finally, may have seen moist conditions and a forest/grassland mosaic throughout the last glacial cycle (Pessenda et al., 2009). As in North America, late-glacial environmental change coincided with extinctions of large mammals.

A likely route of dispersal from North to South America was the Pacific coast, a food-rich littoral zone or ‘kelp highway’ (Erlandson, 2007; Erlandson et al., 2008). A variety of food resources including seals, sea otters, sea urchins, abalone, and numerous species of fish could have been regularly collected along this route, and its relatively calm waters could have facilitated rapid boat travel along this corridor, which may have extended across the north Pacific rim from Japan to California. Rising sea level during the early Holocene submerged much of the late Pleistocene coastal strip, however, creating an archaeological record that is difficult to access (Fedje et al., 2004). Nonetheless, early humans are known to have occupied the Channel Islands by Clovis times, implying the use of seafaring technology at this early date (Erlandson et al., 2008). Archaeological survey of submerged coast lines – in the west and the east – will be an important feature in future first Americans research (Bicho et al., 2011).

Chronology of Human Arrivals

As discussed above, dispersal to the Americas had to have occurred between 40 000 and 13 000 cal BP. The precise timing of initial peopling is still debated; some argue that it occurred before the LGM and coalescence of the Canadian ice sheets (e.g., Madsen, 2005), ~28–24 ka (Clague et al., 2004; Dyke et al., 2002), while others contend that it occurred after the LGM upon reopening of the western Canadian ice-free corridors, ~16–14 ka (e.g., Goebel et al., 2008). Further, some archaeologists still hold that dispersal may not have begun until 14–13 ka, with the appearance of Clovis across North America representing the initial founding event (e.g., Haynes, 2005). The difference of opinion is largely based on a less than secure ‘pre-Clovis’ archaeological record.

The Case for Pre-LGM Colonization, >28 ka

To colonize the Americas, modern humans first had to conquer the windswept, treeless tundra-steppe of arctic/subarctic Siberia. They appear to have done so by 32–31 ka, according to the archaeological record of a cluster of localities along the Yana River, located high above the Arctic Circle in extreme northwestern Beringia, 71° N latitude (Pitul’ko and Pavlova, 2010; Pitulko et al., 2004). Occurring in a deeply buried deposit of frozen silt, preservation at the Yana sites is remarkable. Beyond heavily worked stone tools made on cobbles and flakes (and formed predominantly into side scrapers) and a few small unifacial points made on blade-like flakes (Figure 2(g)), the Yana RHS locality’s inventory includes well-preserved osseous tools, including beveled foreshafts made on mammoth ivory and woolly rhinoceros horn. Faunal remains are especially abundant and suggest the hunting of mammoth, horse, rhino, bison, reindeer, and hare. At another Yana locality, more than 1000 mammoth bones representing at least 26 individuals have been recovered; this accumulation is thought to be the product of human activity (Basilyan et al., 2011). Across the present-day Bering Strait in eastern Beringia, no unequivocal evidence for pre-LGM humans has been found, but at Bluefish Caves, Yukon, a mammoth bone ‘core and flake’ thought by a few scientists to represent the work of humans have been directly dated to 29–28 ka (Cinq-Mars and Morlan, 1999; Morlan, 2003). Bluefish has many critics, however, and the worked bones generally have been disregarded (Bever, 2001; Dixon, 2001).

South of the Canadian ice sheets, archaeological evidence of pre-LGM human settlement is just as tenuous. At the Topper site, South Carolina, a possible hearth feature and a stone assemblage interpreted as a smashed core and microflake industry have been found in sands dating to as early as 50 000 ka (Goodyear, 2005a,b), but geological investigations suggest that the feature consists of naturally accumulated uncharred plant remains, and the artifacts are likely the product of thermal fragmentation (either from fires or repeated freezing and thawing) (Waters et al., 2009; see also Goebel et al., 2008). Another important complex of sites is represented by La Sena and Lovewell, located in Nebraska and Kansas, respectively. Both contain mammoth remains that have been dated to ~25–21 ka and show signs of taphonomic alteration, including spirally fractured bone fragments, percussion-flaked bones and bone flakes, possible bone-stacking features, and even a polished bone interpreted to represent a fragment of a beveled bone point or foreshaft (Holen, 2006, 2007). These features suggest to Holen (2006, 2007) that humans quarried and flaked the bones while they were fresh, within a few years of the animals’ deaths; however, Haynes and Krasinski (2010) argue that they could be the result of natural processes (e.g., wolf/bear gnawing, animal trampling, sediment deformation, or ice rafting during spring thaws). Their elephant-bone-breaking experiments with stone hammers and anvils created a pattern of impact scars not seen on the La Sena and Lovewell bones. The localities also lack the stone artifacts commonly found associated with flaked mammoth bones in northern Eurasia (Goebel et al., 2008). Another recently discovered site, Miles Point, Maryland, may contain lithic artifacts in a buried context potentially dating ~33–25 ka

Figure 2 Artifacts from sites mentioned in text representative of some of the earliest archaeological complexes of Beringia and the Americas (a, Channel Island barbed point from CA-SRI-512W site, Santa Rosa Island, California, USA; b, Miller point from Meadowcroft Rockshelter, Pennsylvania, USA; c, retouched blade from Friedkin site, Texas, USA; d–e, biface fragments from Friedkin site; f, Chindadn point from Walker Road, Alaska, USA; g, unifacially worked point from Yana RHS, Russia; h, j, blade-like flakes, Schaefer, Wisconsin, USA; i, basally thinned bifacial point from Cactus Hill, Virginia, USA; k, fishtail point from Cerro El Sombrero, Abrigo 1, Argentina; l, fishtail point from Uruguay; m, El Jobo point from Monte Verde, Chile; n, triangular, stemmed point from Caverna de Pedra Pintada, Brazil; o, Great Basin stemmed point from Buhl, Idaho, USA; p, Clovis fluted point from the Simon cache, Idaho, USA (illustrations after: a, [Erlandson et al., 2011](#); b, [Adovasio et al., 1988](#); c–e, [Waters et al., 2011a](#); f, [Hoffecker et al., 1993](#); g, [Pitul'ko and Pavlova, 2010](#); h, j, [Overstreet, 2005](#); i, [Goodyear, 2005a](#); k–l, [Flegenheimer et al., 2003](#); m, [Collins, 1997](#); n, [Roosevelt et al., 1996](#); o, [Green et al., 1998](#); p, [Kohntopp, 2011](#)) (drawing by Joshua Keene).

([Lowery et al., 2010](#)); however, only test excavations have been conducted there, and the site is being actively eroded by shore-line processes. An extensive excavation and geoarcheological study of the site are needed to confirm the preliminary findings.

In South America, arguments for a pre-LGM occupation have been made based on evidence primarily from one site – Toca do Boqueirão da Pedra Furada – a large, high rockshelter in north-eastern Brazil. Its early contents occur in stratified colluvial deposits and include concentrations of flakes and other stone pieces associated with hearth features, charcoal samples from which span from >50 to 17 ka ([Guidon and Arnaud, 1991](#); [Guidon and Delibrias, 1986](#); [Santos et al., 2003](#)). Fragments of pictographs preserved on the rockshelter's walls also have calcite

concretions covering them that have been luminescence dated in excess of 35 ka ([Watanabe et al., 2003](#)). Criticisms of Pedra Furada relate to the formation of the lithic artifacts and features: detractors have argued that Pedra Furada's lithics were naturally broken from high-energy geological processes (rock fall and moving water), and that the concentrations of charcoal represent redeposited natural charcoal from range fires ([Lynch, 1990](#); [Meltzer et al., 1994](#)). Further, independent radiocarbon dating of the rock art at Pedra Furada and other nearby caves suggests these features are late Holocene in age ([Rowe and Steelman, 2003](#)). Despite these differences in interpretation, the work at Pedra Furada continues, with new reports describing open-air sites with possible artifacts as old as those from the original rockshelter excavation ([Boëda, 2010](#)).

In the past, other sites have been proposed to predate the LGM (e.g., Calico, California; Tule Springs, Nevada; Pendejo Cave, New Mexico; and Tlapacoya, Mexico; Pikimachay Cave, Peru), but these have not held up to scientific scrutiny (e.g., Meltzer, 2009; Waters, 1985). The same is true for recent reports of fossilized human footprints in Mexico (González et al., 2006; Huddart et al., 2008; Renne et al., 2005). As with Topper, La Sena/Lovewell, and Pedra Furada, critiques of these sites have typically been made on taphonomic grounds, repeatedly showing that the burden of evidence is not being carried by investigators of the proposed pre-Clovis sites, as it should be (Haynes, 2007a; Haynes and Krasinski, 2010). Despite the presence of humans in northwestern Beringia by 32–31 ka, unequivocal evidence has yet to be found documenting their further dispersal into Alaska and the Americas.

The Case for an Early Late-Glacial Dispersal, 16–14 ka

Evidence for human dispersal soon after the LGM, 16–14 ka, is strong but still not secure. In Beringia, archaeological sites dating to this time have still not been found, despite genetic models predicting that they should be there (e.g., Tamm et al., 2007). The region's earliest late-glacial site, Swan Point, dates to just before 14 ka (Holmes, 2011), but all other early occupations – Berelekh, Ushki, Tuluq Hill, Broken Mammoth, Mead, Upward Sun, Walker Road, Dry Creek, Moose Creek, and Owl Ridge (Goebel et al., 2010; Graf and Bigelow, 2011; Hamilton and Goebel, 1999; Holmes, 2001; Pearson, 1999; Pitul'ko and Pavlova, 2010; Potter et al., 2011; Rasic et al., 2011) – all seem to date between 14 and 13 ka, perhaps too late to have played a meaningful role in the dispersal of modern humans south of the Canadian ice sheets (Bever, 2006). Nonetheless, the emerging record from these sites indicates that biface-and-blade-producing humans existed in the region a millennium before the Clovis era (Hoffecker and Elias, 2007; Figure 2(f)).

Some of the earliest purported sites in North America are just where they are expected – in the northern United States just south of the late-glacial limits of the Canadian ice sheets. Schaefer and Hebior, two sites in Wisconsin, have yielded a few stone artifacts (Figure 2(h) and 2(j)) in association with disarticulated remains of single mammoths. The bones bear cut-and-pry marks presumably made by stone tools, and these come from a sealed, stratified deposit consistently radiocarbon dated to 14.8–14.2 ka (Joyce, 2006; Overstreet, 2005). At Paisley Caves, Oregon, three coprolites with human DNA have been directly dated to 14.9–13.9 ka (Gilbert et al., 2008; Jenkins, 2007; Figure 3). These appear to have been associated with stone tools and perishable artifacts, but other materials from the same deposit have yielded significantly younger radiocarbon ages (Jenkins, 2007), indicating site formation processes at the site are exceedingly complex and require careful consideration.

Other northern sites are less secure but nonetheless compelling. Meadowcroft Rockshelter, Pennsylvania, yielded a stone-artifact assemblage with a small lanceolate biface (Figure 2(b)) presumably dating 15.2–13.4 ka (Adovasio and Pedler, 2004), but discrepancies between these dates and the character of associated faunal and floral remains (i.e., they suggest much warmer conditions than expected) continue to

Figure 3 View of Paisley Caves, Oregon, USA. Photograph courtesy of the Center for the Study of the First Americans.

hamper its potential significance (Haynes, 2005). Three other possible archaeological sites – Mud Lake (Wisconsin), Manis (Washington), and Ayer Pond (Washington) – have yielded modified bones but no stone tools (Johnson, 2007; Kenady et al., 2011; Overstreet and Kolb, 2003; Waters et al., 2011b). The Mud Lake find, dating to 16.9–16.2 ka, is a mammoth ulna with a dizzying array of marks interpreted to be from stone-tool cutting (Johnson, 2007); however, these marks are far more numerous than expected and anatomically misplaced, according to butchery experiments with modern elephant carcasses in Africa (Haynes and Krasinski, 2010). Manis consisted of a disarticulated mastodon skeleton with spirally fractured bones (Gustafson et al., 1979) directly dated to 13.9–13.7 ka, and into one of its ribs had penetrated another bone object, recently CT scanned and interpreted to represent the tip of a mastodon-bone projectile point (Waters et al., 2011b). The inserted bone, however, appears to have splintered into multiple pieces, so that its original form is no longer evident. The Ayer Pond site consists of a partial skeleton of a bison directly radiocarbon dated to 14–13.7 ka (Kenady et al., 2010). Bone surfaces are well preserved, and spiral fractures, percussion marks, and a few surface abrasions interpreted as cut marks are evident on them. The context of the bison remains – in deep-water pond sediments – is problematic, unless humans killed and butchered the animal carcass upon a frozen lake in the winter (Kenady et al., 2010). Despite the deficiencies in these sites – especially the lack of stone artifacts and equifinality in determining the agents responsible for altering the recovered bones – the emerging record from the northern United States suggests the southern fringe of the Cordilleran/Laurentide ice sheets may have been one of the first areas to be colonized by late-glacial Americans.

In the southern United States, three possible early sites have been found and excavated, but again none are secure. At Cactus Hill, Virginia, a lithic assemblage including small polyhedral cores, blade-like flakes, and basally thinned bifacial points (Figure 2(i)) was recovered from a sand-sheet deposit and dated to 20–18 ka (Goodyear, 2005a; McAvoy and McAvoy, 1997). The early occupation was not stratigraphically sealed, however, and segregation of the pre-Clovis assemblage from

later Clovis and post-Clovis components was based on elevational positions of artifacts. Further, dates as young as 10.6–10.2 ka also came from the pre-Clovis component; these inconsistencies in the radiocarbon chronology suggest postdepositional translocation of materials (Goebel et al., 2008; Haynes, 2005). At Page-Ladson, Florida, nine probable stone artifacts were recovered along with remains of extinct fauna, including a grooved mastodon tusk, from a submerged sinkhole (Webb, 2006). Radiocarbon dates suggest an age of ~14.4 ka for the artifact-bearing deposit; however, how these remains became associated in the sinkhole remains an open question (i.e., Were humans occupying the sinkhole, and if so, why are there so few remains, or did their artifacts become emplaced there secondarily?). The Friedkin site in Texas has produced a large assemblage of lithic artifacts (>15 000 pieces) (Figure 2(c)–2(e)), including small cores, bifaces, bladelet fragments, and a polished stone of hematite, and these are associated with optically stimulated luminescence (OSL) dates ranging 17.5–14 ka, but the excavators of the site conservatively placed the age range at 16–13.2 ka (Waters et al., 2011a). Although deeply buried, the site contains no discernible geological stratigraphy, and the pre-Clovis component, referred to as the Buttermilk Creek complex, was not sealed from younger Clovis and late-Paleoindian components, meaning that cultural-stratigraphic boundaries had to be defined arbitrarily, based on presence of time-sensitive artifacts and OSL dates. Despite this, supporting geoarchaeological and chemical studies suggest a secure pre-Clovis component; only a refitting analysis of artifacts from between levels and components is needed to test the proposed chronology for the site.

Late-glacial sites dating 16–14 ka have also been proposed for South America, but most have not survived peer review and redating (Gruhn, 2005; Steele and Politis, 2009). Two, however, are still considered as evidence of humans in the Southern Cone a millennium before Clovis: Arroyo Seco 2 and Monte Verde. Arroyo Seco 2 is located in the Argentinian Pampas, in a low loess dune. Under an early-mid-Holocene occupation with numerous human burials (Politis et al., 2009), archaeologists uncovered remains of extinct ground sloth (*Megatherium* sp.), toxodon (*Toxodon* sp.), and horses (*Hippidion* sp. and *Equus* sp.) directly AMS ^{14}C dated to 14.2–13.8, 13.7–13.3, and 13.2–12.9 ka, respectively (Steele and Politis, 2009). Some of these remains reportedly show signs of cultural modification and were found in association with quartzite artifacts with unifacial, marginal retouch. A final report on the Arroyo Seco 2 excavations is forthcoming (Politis et al., in press; Figure 4). Excavations at Monte Verde, Chile, occurred from 1977 to 1985, and publication of its monumental site report (Dillehay, 1997) was truly a watershed event in Paleoindian studies (Meltzer et al., 1997). The site's earliest cultural component contained unequivocal artifacts – lithic and nonlithic – from a stratified context sealed by a terminal Pleistocene peat deposit, and it was repeatedly ^{14}C dated to ~14.5 ka. Among the materials recovered *in situ* were stone bifacial points and grooved spheres, remains of nearly 70 species of plants, bones of gomphotheres, some still with adhering soft tissue, wooden artifacts (including lances, digging sticks, and stakes), foundations of small huts, and even a human footprint. Despite the site's preservation, questions about its context have been raised. Critics have suggested

Figure 4 View of Arroyo Seco 2, Argentina. Photograph courtesy of Maria Gutierrez.

that most of the well preserved remains accumulated naturally and the handful of clearly recognizable artifacts represent a later occupation and were intrusive into the 14.5-ka layer (Fiedel, 1999; Haynes, 1999; Lynch, 1990). Dickinson (2011) further points out the inferred age of the Monte Verde occupation suggests it was coeval with local deglaciation and the site thus would have been in a periglacial setting, potentially contradicting its rich paleobotanical record. Nonetheless, Monte Verde still is the strongest candidate for a late-glacial-aged pre-Clovis site in the Americas.

As the above review of sites attests, the evidence for humans in the Americas before the time of Clovis continues to mount. The stone tools associated with proboscideans from Wisconsin, ancient human coprolites from Oregon, extensive Buttermilk Creek complex from Texas, and well-preserved Monte Verde occupation from Chile strongly suggest human presence in both North and South America by 15–14 ka and possibly earlier. Continued research at these plus other important sites like Arroyo Seco 2 may eventually prove an early late-glacial colonization of the Americas, which is seemingly corroborated by current genetic models calculating the timing of human dispersal from Beringia to the rest of the Americas by 15 ka (Perego et al., 2010; Tamm et al., 2007). Evidence from even earlier sites as these, however, may force further revision of this date.

Physical Anthropology

Without doubt, human skeletal evidence across the Americas shows that modern *H. sapiens* colonized the New World. Their remains come from a multitude of archaeological sites dating as early as 13 ka. In North America, among the earliest are Arlington Springs (13.1–12.6 ka), California; Anzick (12.7–12.5 ka), Montana; Buhl (12.4–11.8 ka), Idaho; and Arch Lake (11.8–11.3 ka), Texas (Green et al., 1998; Johnson et al., 1999; Morrow and Fiedel, 2006; Owsley et al., 2010; Stafford et al., 1987). In Mexico, the Peñon remains date to 12.8–12.5 ka, and several nearly complete, well-preserved human skeletons possibly dating as early as 13.7 ka have been recovered from three submerged Yucatan cenotes (underwater

sinkholes) named Naharon, Las Palmas, and Aktun Ha (Gonzalez, 2006; González González et al., 2008). In South America, many remains of early humans have also been recovered, most notably nearly 100 individuals from the Lagoa Santa region of eastern Brazil, most dating around 10 ka, including the Luzia skull (Lapa Vermelha IV) possibly dating as early as 11.4 ka or earlier (Araujo et al., 2008; Feathers et al., 2010; Neves et al., 2007b). These and other human remains spanning the terminal Pleistocene and early Holocene provide an opportunity to examine the origins and adaptations of the earliest Americans.

Recent paleoanthropological studies indicate that the first Americans were physically quite variable, leading some to speculate that they represent two migrations from more than one source (e.g., Neves et al., 1999). Through multivariate comparisons, in the late 1990s, several paleoanthropologists studying the human skeletal remains from Spirit Cave (Nevada) and Kennewick (Washington) found that their crania were 'narrow and long' like modern Europeans, not 'broad and round' like modern Native Americans and northeast Asians (Jantz and Owsley, 1997; Lahr, 1997). They labeled these individuals as 'Caucasoid,' and the media quickly disseminated the concept of a European origin for Kennewick man. Continued craniometric studies reinforced these interpretations of a highly variable 'Paleoamerican' population that was significantly different from later Amerindians, but with an ever-increasing sample it soon became clear that the 'Paleoamericans' were much more similar to modern Ainu and prehistoric Jomon populations of Japan as well as southeast Asian populations in general, suggesting an ancestral-descendant relationship with ancient Asians, not Europeans (Brace et al., 2001; Chatters et al., 2000; González-José et al., 2003, 2005; Lahr, 1995; Neves and Hubbe, 2005; Neves et al., 2004, 2007b; Powell and Neves, 1999; Steele and Powell, 2002; Figure 5). According to

Figure 5 Principal components chart showing variability in craniometrics of early North and South Americans, in context of more recent modern human populations. Reproduced from Powell JF (2005) *The First Americans: Race, Evolution and the Origin of Native Americans*. Cambridge: Cambridge University Press.

some paleoanthropologists, the craniometric differences between Paleoamericans and more recent Amerindians are best explained through a two-migration model, with Paleoamericans being replaced by Amerindians sometime during the terminal Pleistocene or early-mid-Holocene (Hubbe et al., 2010; Neves and Hubbe, 2005; Neves et al., 1999, 2007a). The Kennewick man had the tip of a stone spearpoint imbedded in his right hip (Chatters, 2002), could this be evidence of struggle between the two populations?

Other lines of evidence do not support the replacement theory. Genetic models based on extant human populations as well as empirical evidence from ancient DNA overwhelmingly imply a single dispersal out of Beringia, not two or more (Perego et al., 2010; Raff et al., 2011; Schroeder et al., 2009). According to Hubbe et al. (2010), the genetic studies are misleading, because they have not included mtDNA from ancient Paleoamerican populations and perhaps because the variation in Native American DNA was the product of different microevolutionary events than those that led to the measured differences in cranial shape. However, the few Paleoamericans that have been tested genetically do bear Amerindian mtDNA lineages (Raff et al., 2011), and even in southern South America, a combined study of craniometrics and ancient DNA failed to demonstrate a genetic change across the Paleoamerican–Amerindian transition in cranial morphology (Perez et al., 2009). The archaeological record is also mute regarding a Paleoamerican–Amerindian transition. A rupture in lithic technology, tool forms, or lifeways is expected coincident with this transition. In the intermountain west of the United States, where human skeletons representing both conditions have been dated to 12.4–10.2 ka, there is no evidence for synchronous competing cultures, and no recognized archaeological transition at any time during this period (Goebel et al., 2011). Changes in technology and subsistence did occur before 12.5 ka and after 10 ka (i.e., the Clovis-to-stemmed-point transition and stemmed-to-notched-point transition, respectively), but these did not coincide with changes in skull morphometrics. The same is true for other regions of North America. More likely change between Paleoamericans and Amerindians is the product of drift and selection, not migration and replacement (González-José et al., 2008; Powell, 2005). If multiple migrations did occur, then the mtDNA of the original American population has been eradicated, or the two dispersals occurred simultaneously from the same genetic source in Beringia (Perego et al., 2009).

Impact of Humans on Environments

The role of humans in the extinction of Pleistocene megafaunal species has been debated for decades (Barnosky et al., 2004). Traditionally, polarized scientific positions saw either humans or climate as the driving force behind extinctions (e.g., Grayson, 1989; Grayson and Meltzer, 2002, 2003; Martin, 1967, 1984), but recently other theories, for example, the spread of disease among megafauna (MacPhee and Marx, 1997) and a catastrophic meteor impact (Firestone et al., 2007) have been proposed to account for some large animal disappearances. New studies combining genetic, paleontological, and archaeological data indicate, however, that individual megafaunal species

responded differently to end-of-the-Pleistocene changes in climate, habitat distribution, and human predation (Lorenzen et al., 2011). There is no ‘one-size-fits-all’ model explaining megafaunal extinctions.

In northeast Asia, roles of climate and humans in faunal extinctions varied. While the disappearance of musk ox and woolly rhinoceros was likely driven by climate alone, the extinction of steppe bison and dramatic reduction in the range of horses were affected by both climate and humans (Lorenzen et al., 2011). Late Upper Paleolithic Siberians regularly hunted on horse and bison for thousands of years (Goebel, 2002; Guthrie, 1990), and even in Alaska, remains of these taxa occur in the earliest site, Swan Point (Holmes, 2011). After the LGM, woolly mammoths occur in relatively few Siberian archaeological sites, potentially reflecting a northward-shifting range for this species that could have been caused by breakdown of the tundra-steppe in the south (Lorenzen et al., 2011). In late-glacial Beringia, mammoth remains – primarily tusk fragments – occur at Berelekh, Swan Point, and Broken Mammoth (Holmes, 2011; Mochanov, 1977; Yesner et al., 2011), but this may mean that humans were mining old mammoth ivory and bone for use as tools, not regularly hunting live animals (Yesner, 2007).

In North America, at least 17 of 35 mammal species became extinct ~13 ka, coincident with the time of the Clovis complex (Faith and Surovell, 2009; Haynes, 2007b). The role of humans in many of these extinction events may have been negligible (Grayson and Meltzer, 2002, 2003), and even in Clovis sites like Colby (Wyoming) and Lehner and Murray Springs (Arizona) where extinct fauna (e.g., American camel (*Camelops*) and horse (*Equus*)) have been found, it is difficult to prove that the remains resulted from human hunting (Haynes, 2007b). But the record for repeated mammoth/mastodon hunting in late Pleistocene North America cannot be ignored: “at least 14 kills of proboscideans were made and have been preserved from a period possibly lasting only 300 years, far more in number than on any other continent and far more in such a brief time interval than in all of prehistory” (Haynes, 2007b, p. 89, italics in original). Humans did hunt mammoth and mastodon in late Pleistocene North America, and quite possibly, they did play a significant role in their extinction.

In South America, the timing of most late Pleistocene megafaunal extinctions was coeval with those in the north (Barnosky and Lindsey, 2010; Borrero, 2008). Twelve of 15 species that became extinct did so after the appearance of humans on the continent, and for ten of these extinctions occurred during the first 1000 years of documented human prehistory. So far, remains of extinct fauna including giant ground sloths (*Glossotherium* sp., *Megatherium* sp., and *Mylodon* sp.), horse (*Equus* sp. and *Hippidion saldiasi*), toxodon (*Toxodon* sp.), extinct camelids (*Hemiauchenia* sp. and *Paleolama* sp.), and giant armadillo (*Glyptodon* sp.) have been recovered from Paleoindian sites like Quebrada Santa Julia (Chile) and Pasa Otero 5 (Argentina) (Jackson, 2003; Jackson et al., 2007; Martínez, 2001; Massone, 2003; Miotti and Cattáneo, 2003; Miotti et al., 2003; Paunero, 2003; Vialou, 2003). Many of these remains show signs of having been butchered, but others may represent mining of old bone, like in Beringia (Borrero, 2006). In some areas, for example Brazil, multiple species disappear from the fossil record simultaneously with human

colonization, whereas in other areas, for example, the Southern Cone, some species persist for a thousand years or more (Barnosky and Lindsey, 2010). Given that end-of-the Pleistocene climate changes affected South America’s varied environments in different ways, as in the Northern Hemisphere processes of megafaunal extinctions may have been species-specific and regionally variable, with humans potentially playing variable roles.

Certainly, Paleoindians intentionally transformed other aspects of the New World’s ‘virgin’ environments. Some effects were subtle, for example, the artificial redistribution of lithic materials across landscapes (Borrero, 2011) or the artificial concentration of productive plant species in the Neotropics (Gnecco, 2003a,b; Piperno, 2009), but others may have been dramatic, most notably the intentional setting of range fires to promote productive plant and animal communities (Pinter et al., 2011). Later Native North Americans practiced this resource management strategy (Keeley, 2002), and in the Neotropics, horticulturalists practiced slash-and-burn agriculture as early as 6–5 ka (Arroyo-Kalin, 2012). Vegetation records for the end of the Pleistocene show significant increases in charcoal and fire-driven revegetation, and while most paleobotanists interpret this to have been the result of natural fire-regime changes (Marlon et al., 2009; Power et al., 2008), Pinter et al. (2011) suggest that the increase in fire activity is time-transgressive across the Western Hemisphere and, perhaps, correlative to the appearance of a ‘new and significant ignition source’ – humans.

Technology and Economy

The Schaefer and Hebior sites provide strong evidence that humans existed in North America by 14.8–14.2 ka, synchronous with the early finds from Monte Verde, Chile. If the finds from Paisley Caves, Meadowcroft Rockshelter, Page-Ladson, and Friedkin are confirmed with additional work or clear reporting, together they would suggest that biface-, blade-, and bone-tool-making technologies were established in North America at least 1000 years earlier than Clovis (Waters et al., 2011a). The well preserved remains from Monte Verde indicate that early Americans also used perishable materials like wood and fiber as tools (Dillehay, 1997). Less is known about pre-Clovis subsistence and settlement. Schaefer, Hebior, Monte Verde, and Page-Ladson contained remains of mammoth or mastodon, but whether any of these resulted from human predation currently cannot be proven. At Monte Verde, however, exotic sediment was found embedded in the mastodon bones, suggesting humans had scavenged carcass parts, transporting them back to the site (Borrero, 2008). Monte Verde also contained a rich array of floral remains, including rhizomes, tubers, seeds, fruits, and nuts, presumably consumed by its occupants indicating a broad diet, and preserved features interpreted as dwellings indicate a stationary residence (Dillehay, 1997).

We know much more about early American technology and economy during the Clovis era, 13.3–12.8 ka. Clovis people regularly used stone bifacial technology to prepare weapon tips and blade technology to prepare a variety of unifacial tools like scrapers, knives, and graters (Bradley et al., 2010; Tankersley,

2004). The Clovis fluted point typifies the complex – both its lanceolate, concave-based form, and the particular broad fluting and overpass flaking that characterize its technology (Figure 2(p)). Clovis people also regularly produced osseous tools (made of bone, antler, or ivory), including cylindrical rods beveled at one or both ends and functioning as projectile points or foreshafts. Most Clovis stone tools were manufactured on high-quality cherts and obsidians often procured hundreds of kilometers from where they were last used and discarded (Tankersley, 2004). The long-distance transport of prepared cores and tools, together with the repeated caching of these artifacts at sites like East Wenatchee and Simon (Kilby, 2011), suggest that in some areas of North America, Clovis people were highly mobile (Tankersley, 2004). In Texas and the southeastern United States, however, dense concentrations of Clovis artifacts at sites like Gault and Topper have been interpreted to represent quarry-campsites suggesting significantly lower degrees of mobility (Smallwood, 2010; Waters et al., 2011c). In terms of subsistence, Clovis people appear to have regularly hunted mammoth and mastodon as well as scavenged their remains (Haynes, 2002, 2007a,b); however, they also are known to have taken bison, deer, hares, reptiles, and amphibians (Cannon and Meltzer, 2004). At Shawnee-Minisink, Pennsylvania, carbonized seeds of ten different kinds of plants, including hackberry, blackberry, hawthorn, plum, and grape, as well as calcined fish bones were recovered from hearths associated with Clovis artifacts and dated to 12.9–12.6 ka (Figure 6; Dent, 2007; Gingerich, 2011). Clovis certainly represents a temperate North American phenomenon, but Clovis-like bifaces have been recovered as far south as Mexico, Panama, and possibly even Chile, suggesting the technology and possibly even the people dispersed well south of the modern US border (Gaines et al., 2009; Jackson, 2006; Ranere, 2006).

Other late Pleistocene archaeological complexes are still rich in bifaces, but blade and osseous technologies are less common. In the far west of North America, large stemmed-and-shouldered bifacial points (Figure 2(o)) replaced fluted

points as the primary projectile-point form (Beck and Jones, 2010), whereas in the Great Plains and eastern United States other fluted-point forms (e.g., Folsom, Gainey, Cumberland) appear to have succeeded Clovis (Anderson et al., 2010; Stanford et al., 2005). Long-distance transport of lithic materials and manufacture of formal flake-tool forms continued to characterize these complexes, however (Ellis et al., 2011; Jones et al., 2003). In the desert west, excavations in dry caves and rockshelters like Bonneville Estates Rockshelter and Spirit Cave have revealed rich perishable technologies of bone needles and awls, fiber cordage, and fiber textiles including baskets, bags, and baskets (Connolly and Barker, 2004; Fowler et al., 2000; Goebel et al., 2011; Jenkins, 2007).

By 12.5 ka, human diets across North America had become quite diverse. On Santa Rosa Island off the coast of California, by 12–11.8 ka humans producing small barbed points (Figure 2(a)) had accumulated middens full of remains of waterfowl and sea birds, pinnipeds, and other sea mammals, marine fish, and marine shells (Erlandson et al., 2011). In the Great Basin, humans regularly took artiodactyls like deer, pronghorn antelope, and bighorn sheep but also relied on small mammals (e.g., hares), grouse, waterfowl, and even insects (e.g., grasshoppers), and fish (salmon) (Goebel et al., 2011; Hockett, 2007). At Dust Cave, Alabama, late Paleoindians processed hickory and acorn nuts, collected seeds and fruits, and hunted a variety of animals, chiefly birds, and they even cached 23 Canada goose (*Branta canadensis*) humeri representing at least 12 individuals (Walker, 2010; Walker et al., 2007). Similarly, diverse diets have been documented for other regions of the continent. Residential sites with preserved remains of dwellings are rare but have been found at several Folsom sites in Colorado (e.g., Mountaineer and Barger Gulch) (Stiger, 2006; Surovell and Waguespack, 2007) as well as at a stemmed-point site in Oregon (Paulina Lake) (Connolly and Jenkins, 1999).

In South America, besides the rich inventory of organic artifacts recovered from Monte Verde (described in Section

Figure 6 A hearth feature shown in profile (a) with inset (b) of charred hawthorn seeds from the Shawnee-Minisink Clovis site, Pennsylvania, USA. Photographs courtesy of Joseph Gingerich.

'The Case for an Early Late-Glacial Dispersal, 16–14 ka'), most of our knowledge of Paleoindian technology is based on lithics. Fishtail bifacial points (Figure 2(k) and 2(l)), often fluted, seemingly dominate the Paleoindian record, but other projectile forms also occur including stemmed points of the Paijan complex in Peru, and leaf-shaped El Jobo points of Monte Verde (Figure 2(m)) and other early sites (Bryan et al., 1978; Dillehay et al., 2003, 2004), and barbed points at Pedra Pintada, Brazil (Figure 2(n)) (Roosevelt et al., 1998). Milling stones appear in some regions as early as ~12 ka (Dillehay et al., 2003; Gnecco, 2003a,b), as do sophisticated textiles and cordage (Jolie et al., 2011; Sandweiss et al., 1998). Increasingly broad diets are also evident: by the late Paleoindian period, ~12.5–12 ka, Amazonians at Pedra Pintada, were fishing and collecting tree fruits (Roosevelt et al., 1996; Figure 2(n)), while humans along the Pacific coast of Peru at Quebrada Jaguay had developed a specialized maritime adaptation that focused on net fishing for drums (*Sciaenae*) and collecting wedge clams (*Mesodesma donacium*) (Sandweiss et al., 1998). In the Southern Cone, at sites like Agua de la Cueva and Piedra Museo, late Paleoindians regularly hunted extant camelids and gathered eggs of the large flightless bird *ñandú* (Rheidae) (García, 2003; Miotti and Cattáneo, 2003). These Patagonian Paleoindians habitually transported tool stones long distances (Flegenheimer et al., 2003); however, in Peru, late Paleoindians increasingly turned toward local raw materials, presumably as territories shrunk and more permanent camps were developed (Dillehay et al., 2003). As in North America, the variety of archaeological complexes and presence of Paleoindian sites across the continent tell us that humans rapidly settled into South America's varied environments, by 13–12 ka.

Summary

Genetic evidence strongly suggests all Native Americans – past and present – originated in greater northeast Asia. Modern humans appeared in Siberia and eastern Asia by 40 ka, and dispersal from this homeland to the Americas may have begun before the LGM. The colonization process, however, appears to have stalled in Beringia for 10 000 years or more. There the earliest archaeological site, Yana RHS, dates to ~32–31 ka, but after this, the next earliest site dates to only ~14 ka. During the Late Glacial, 16–14 ka, Beringians seemingly dispersed south through two corridors that opened as the great ice sheets of western Canada retreated. One route of colonization may have been the northwest Pacific coast, while another was along the eastern flank of the Canadian Rocky Mountains. A few archaeological sites like Paisley Caves, Schaefer/Hebior, and Friedkin in North America and Monte Verde in South America suggest the presence of humans south of the ice sheets during this time, but it is not until the Clovis era, ~13 ka, that a consistent pattern of occupation emerges. Sites with Clovis artifacts occur across temperate North America and Mexico, possibly even as far south as Panama or Chile.

Genetic evidence combined with studies of early human skeletal remains suggest that only a single dispersal event out of Beringia occurred during the late Pleistocene. Humans spreading via both the coastal and interior corridors may

have done so from the same northern source, at roughly the same time. Although early Americans were craniometrically diverse, this variability is not surprising given the genetic mechanism of founder effect. Apparent similarities with modern southeast Asians more likely reflect the late Pleistocene relationship early Americans had with most early modern Asians, a relationship obscured by later Holocene craniofacial evolution resulting from dietary changes and other selective forces.

The first Americans dispersed rapidly, and by 13–12 ka they had successfully adapted to most of the New World's varied environments, including the Neotropics and Southern Cone of South America. In some settings, humans may have contributed to extinctions of Pleistocene megafauna. Clovis hunters, for example, regularly preyed on mammoth and mastodon, and in southern South America, there are repeated associations of artifacts and remains of extinct animals like giant ground sloth and giant armadillo. In other contexts, though, these animals were not the basis of Paleoindian subsistence, and it is clear that some early Americans subsisted on a variety of animal and plant species, most of which are still in existence today.

Although much is known about the late Quaternary dispersal of humans to the Americas, most details about the process remains to be discovered. In Beringia, for example, geologists and archaeologists from two continents still must work together to reveal the initial episode of colonization. New discoveries elsewhere in the Americas, as well as the development of new methods in genetics, archaeology, and Quaternary paleoecology, will undoubtedly lead to a more comprehensive and detailed portrayal of this important event in the history of the human species.

Acknowledgments

Special thanks to Scott Elias and Clive Gamble, who were extremely patient as I prepared this chapter. Also, thanks to Kelly Graf, Tom Jennings, and Ashley Smallwood, who provided helpful comments on an earlier draft. Joshua Keene prepared Figure 2, and Heather Smith helped prepare Figure 6.

Introduction

The last 2 My have seen the evolution and development of one of the most unique genera to have ever existed, *Homo*. Despite the presence in the fossil record of a wide range of hominin species, *Homo sapiens* is now the only living representative of this genus. It can also be considered one of the most successful, being the most populous and geographically diverse of all the hominins. Over a relatively short space of time, *Homo* has evolved from ape-like origins to become the most technologically sophisticated of all animals, and unique within the primate order in terms of its complex symbolic cognition. The evolutionary processes from which the unique human species emerged are necessarily complex and often frustratingly inscrutable. Only by studying the available fossil, lithic, faunal, and environmental evidence will it be possible to start to tease apart the hows, wheres, whys, and whens of hominin evolution and begin to understand the unique position of the genus *Homo* in the Primate order and the reasons why *H. sapiens* ultimately out-survived all other hominin species.

The article is split into four sections, covering the major evolutionary milestones in the development of the human genus. Section 'The Emergence of *Homo*' will deal with the emergence of *Homo* at the beginning of the Quaternary Period, from a landscape that was unique in containing a number of competing species, only one of which would be the ancestor of all other members of *Homo*. Section '*H. erectus* and the First Human Expansions' will discuss a key watershed in the evolution of *Homo*, the appearance of *H. erectus*, and cover the first expansions of *Homo* outside Africa, an event which appears to have taken place almost as soon as the genus first appeared. Section 'The "Transitional" Hominins' will focus on what can be considered 'transitional' hominins, those species who succeeded *H. erectus* and paved the way for later *H. sapiens*. This section will also deal with the most well known of all the hominin cousins, the Neanderthals. Finally, section 'The Appearance of *H. sapiens*' will look at the emergence of *H. sapiens* and the factors that resulted in modern humans becoming the last surviving member of the human genus. It will also look at the recent surprising discovery of *H. floresiensis*, which suggests that *H. sapiens* has not been alone for as long as first thought.

The Emergence of *Homo*

Around the start of the Quaternary Period, approximately 2Ma, it is believed that there were at least five species of hominins living in southern and eastern Africa: *Paranthropus robustus*, *P. boisei*, *Australopithecus sebidia*, *H. habilis*, and *H. rudolfensis* (and possibly also *H. ergaster*; see Figure 1; Wood and Lonergan, 2008). Although most of these species were ultimately evolutionary dead ends, one of these

species became the ancestor of all other members of the genus *Homo*. The exact identity of this ancestral species is not certain, but many believe the most likely candidate to be *H. habilis*, or the closely related *H. rudolfensis*. *H. habilis* is widely thought to be the first member of *Homo* and was first identified from material found at Olduvai Gorge, Tanzania (Leakey, 1961; Leakey et al., 1964). The discoverers of the OH 7 (Olduvai Hominid 7) specimens noted its 'modern' suite of traits when compared to *Australopithecus*, such as increased cranial capacity (estimated between 642 and 732 cc by Tobias (1964)), more gracile mandibular teeth, and modern-like morphology of the hand bones. It was this modern morphology (particularly in the hands) and the discovery of OH 7 in an archaeological context associated with Oldowan stone tools (the earliest identified hominin stone tool industry, discovered at Olduvai Gorge and named after this area) that lead to this new species being placed at the root of the human family tree. This name given to this species, *H. habilis* ('Handy Man' in Latin), highlights the importance that was placed on stone tool use and manufacture as a defining characteristic of being 'human.'

As subsequent fossil finds were assigned to this new species it became increasingly apparent that *H. habilis* contained a larger amount of variation than might be considered reasonable, typified by the differences seen in cranial size and facial morphology between skulls from the Kenyan site of Koobi Fora, KNM-ER 1470 and KNM-ER 1813 (see Holloway et al., 2004). These differences have led to the KNM-ER 1470 specimen and others being assigned to *H. rudolfensis* (Wood, 1992, 1999). The precise nature of the relationship between these two species is unclear, complicated by a general lack of post-cranial material (i.e., parts of the skeleton other than the skull) attributed to either species and a lack of consensus on the amount of variation these species should accommodate. How *H. habilis* and *H. rudolfensis* interacted with both their contemporaries and their likely successor, *H. erectus* is not known. It is likely that there would have been competition for resources within a given area and therefore pressure to find new avenues through which to exploit their environments. This is certainly suggested in the range of morphology displayed across these species, in particular in the megadont (large-toothed) *Paranthropus* species. It may also have been this resource competition that encouraged early hominins such as *H. habilis* and *H. rudolfensis* to develop a specialization for the use and manufacture of stone tool (lithic) technology, to gain an advantage which ultimately allowed them to expand into and dominate new niches. There is also evidence to suggest that climatic change in Africa between 3 and 2Ma would have further impacted on the interspecies competition (Klein, 2009).

The timings of the first appearance datum (FAD) and last appearance datum (LAD) of *H. habilis* and *H. rudolfensis* are important for understanding the ancestry of *Homo*

Figure 1 Timeline of hominin evolution. Based on data from Wood and Lonergan (2009). Used with permission from M. Grove.

(see Figure 1). It has been proposed by some that *H. habilis* is the most likely ancestor of *H. erectus* (e.g., Lieberman et al., 1996; Wood, 1991). If ancestry is based on cranial size, however, then the larger inferred brain size of *H. rudolfensis* places it on the path to *H. erectus*, to the exclusion of *H. habilis* (Klein, 2009). An alternative view sees both *H. habilis* and *H. rudolfensis* as a side branch of the hominin family tree, which evolved in parallel with *H. erectus*, but did not evolve into *H. erectus* (Wolpoff, 1999). This view holds that the variation shown by *H. habilis* and *H. rudolfensis* falls within that seen in the Australopithecines (Wood and Collard, 1999).

The exclusive association made by Leakey et al. (1964) between *H. habilis* and Oldowan tools has been questioned since the species was first described. The discovery of lithic artifacts dating back to around 2.6 Ma (Semaw et al., 1997) implies a much earlier emergence of *Homo* that is supported by the fossil evidence. Despite this, there has been little evidence linking *Australopithecus* or *Paranthropus* to the manufacture of these first stone tools, despite the inference that these early Oldowan tools look too 'well made' to represent the first appearance of lithic flaking technology and that the first tool makers are likely to have preceded *Homo* (Braun, 2010). Recently, animal bones bearing scratches attributed to tool use have been found in Dikika, Ethiopia and dated to at least 3.2 Ma (McPherron et al., 2010). The location of these bones, ~300 m from the site of the

discovery of a juvenile *A. afarensis* skeleton (Alemseged et al., 2006) strongly suggests a non-*Homo* manufacturer. While persuasive, the interpretation of these scratch marks as being made by tools (rather than natural causes) has been questioned (Dominguez-Rodrigo et al., 2010).

At the time of the discovery of *H. habilis*, the notion that it represented the first member of *Homo* was disputed. Some believed that the material attributed to *H. habilis* could be reasonably included inside either *Australopithecus* or *H. erectus* (Brace et al., 1973; Robinson, 1960, 1965, 1966). More recently, it has been again proposed that *H. habilis* (and *H. rudolfensis*) are not reliable species and that both should be reclassified within *Australopithecus* (Wood and Collard, 1999). Wood and Collard propose that species should only be included in *Homo* if there are found to be more similar to *Homo* than *Australopithecus* in five key regards: (1) estimated body mass, (2) body proportions, (3) a postcranial morphology adapted to obligate bipedalism with limited capacity for climbing, (4) mandibular and dental morphology, and (5) period of growth and development (i.e., childhood). Based on this definition, *H. habilis* and *H. rudolfensis* do not match the criteria for inclusion in *Homo*, and if they were to be members of the genus then *Homo* would no longer be a 'good' genus, understood by the authors to be "a monophylum whose members occupy a single adaptive zone" (Wood and Collard, 1999,

p. 70). For that reason, these species are reassigned as *A. habilis* and *A. rudolfensis*. Based on this reclassification, the earliest bona fide species of the genus *Homo* would be *H. erectus*, which can be indisputably defined as *Homo* based on Wood and Collard's criteria.

H. erectus and the First Human Expansions

The appearance of *Homo* in Africa saw an almost immediate migratory move toward new environments in Asia. This migration and expansion appears to have been carried out by a new member of the human genus, *H. erectus*. This species differed from *H. habilis* and *H. rudolfensis* in that it was the first member of *Homo* that can be considered to have a truly modern-like morphology (Wood and Lonergan, 2008) and it may have been this morphological 'modernity' that facilitated this dispersal.

The species known as *H. erectus* was first identified from fossil material found by Eugene Dubois at Trinil in Java, Indonesia toward the end of the nineteenth century. These fragmentary remains (consisting of a left femur and calvaria (skull cap)) were named *Pithecanthropus erectus*, reflecting the modern morphology of the femur ('erectus' meaning 'upright') but the primitive nature of the skull cap. Subsequent fossil finds from this region were attributed to *Pithecanthropus*, with specimens found in China attributed to *Sinanthropus pekinensis* (Klein, 2009). At the same time, as fossils of early *Homo* were being discovered in eastern Asia, similar specimens were starting to be found in Africa (Cartmill and Smith, 2009). By the 1950s, the idea had been presented that both *Pithecanthropus* and *Sinanthropus* should be subsumed into *Homo* (e.g., Mayr, 1950), and by the 1960s, the classification *H. erectus* became accepted terminology for both the Asian and African material (e.g., Howell, 1960; Howells, 1966).

Despite first being found in Asia, radiometric dating now suggests that the *H. erectus* originally emerged within Africa. Of the African specimens, those that can be definitively be assigned to *H. erectus* come from the Koobi Fora site in Kenya and are dated to around 1.8–1.7 Ma (Cartmill and Smith, 2009). Some fragmentary pelvic and occipital bone material, also from Koobi Fora, has been dated to between 2 and 1.95 Ma, but there is some debate as to whether this material can be reliably assigned to *H. erectus* (Cartmill and Smith, 2009; Klein, 2009). The dating of the Asian *H. erectus* specimens is trickier, due to the nature of the discovery of some of the earlier finds, which were collected rather than excavated, and due to the complicated stratigraphic context in which the fossils have been found (Cartmill and Smith, 2009). Addressing the debate around dating of the Javanese samples, Langbroek and Roebroeks (2000) question the older FAD of between 1.8 and 1.6 Ma proposed by Swisher et al. (1994) and reattribute the fossils from the Javanese site of Sangiran to between 1.1 Ma and 780 ka.

Claims have been made that *H. erectus* was present in China as early as 1.9 Ma, at the site of Longgupo (Huang et al., 1995). That the limited mandibular and dental remains found at this site can be attributed to *Homo* has been disputed (e.g., Wolpoff, 1999), and more reliable evidence for the first human occupations of modern-day China comes from the Nihewan Basin,

although this is based only on lithic material dating to 1.36 Ma (Zhu et al., 2001). In addition, the major site of Zhoukoudian, while challenging to date, has providing dates of between 669 and 280 ka (based on electron spin resonance) and around 400 ka (based on thermal-ionization mass spectrometry) for its fossil-bearing layers (Grün et al., 1997; Huang et al., 1991). While dating of these eastern Asia sites remains problematic, together these data support the notion that *H. erectus* first appeared in Africa before migrating toward eastern Asia (see Figure 1).

The appearance of *H. erectus* in the fossil record marks a significant advance in hominin evolution, as they are the first species that unequivocally display modern-like body proportions and a commitment to bipedalism with an upright posture (although their brain capacities were considerably less than in modern *H. sapiens*; Wood and Lonergan, 2008). Table 1 summarizes some of the key traits of *H. erectus* (both African and Asian) which distinguishes it from both earlier hominins and later *H. sapiens*.

While *H. erectus* displays a degree of expansion in cranial size, it is worth noting that much of this expansion can be explained by the clear increase in body size in this species, suggesting that *H. erectus* may have exhibited only a limited leap in cognitive capabilities, albeit a leap that appears to have prompted the development of a stone tool industry, the Acheulean (Klein, 2009).

The postcranial skeleton of African *H. erectus* is best known from the relatively complete skeleton of KNM-ER WT 15000, also known as the Nariokotome Boy (Walker and Leakey, 1993). This skeleton is thought to be from a juvenile between 10 and 15 years old at time of death (Smith, 1993), although more recently his age has been estimated at as young as 8 years old (Dean and Lucas, 2009). His morphology was found to be very modern-like and if he had reached maturity, he would have attained an adult height of 185 cm (6 ft) tall (Ruff and Walker, 1993). The long limb bone proportions and adaptations for obligate bipedalism in this individual suggest that *H. erectus* was better adapted to long-distance walking, and perhaps endurance running, than any other previous hominin (Bramble and Lieberman, 2004). By comparison, the postcranial morphology of Asian *H. erectus* is not well known, with

Table 1 Key diagnostic features of *Homo erectus* (African and Asian)

<i>Craniofacial characteristics</i>
Average cranial capacity of ~900 cm ³
Low cranial vault height, with thick walls
Continuous supraorbital torus
Occipital bun
Reduced postcanine dentition and jawbone robusticity, relative to earlier hominins, but larger than seen in later <i>Homo</i>
Reduced number of roots on maxillary premolars
More modern dental eruption schedule
Vertical shortening of face
Lack of 'chin' (compared to <i>H. sapiens</i>)
<i>Postcranial characteristics</i>
Modern-like postcranial proportions
Increased cortical bone thickness
Anterior–posterior femoral flattening, with mediolateral tibial flattening
Absence of pilaster muscle insertion on femur

Based on Cartmill and Smith (2009), Klein (2009), and Wood and Lonergan (2008).

only limited remains having been found to date. Only those remains found in Zhoukoudian can be firmly associated with *H. erectus* and their morphology appears to be similar to that seen in African *H. erectus* (Cartmill and Smith, 2009).

A degree of variation has been identified between the African and Asian material, and this has led some researchers to propose that the individuals in these regions in fact represent two separate species, *H. erectus* in Asia and *H. ergaster* in Africa (Andrews, 1984; Stringer, 1984; Wood, 1984). The reasons behind the separation of *H. ergaster* from *H. erectus* are based not only on the greater age of the African material, but also on the features of *H. ergaster* cranial morphology that are considered less derived than those seen in Asian *H. erectus*, particularly in the mandibular premolars and features of the cranial vault and base (Wood and Lonergan, 2008). The splitting of these species leaves only a small number of individuals within *H. ergaster*, dating to between 1.9 and 1.5 Ma (Klein, 2009). Such splitting has also been criticized on the basis that the level of variation seen between the fossils can reasonably be considered within-species variation (Gabunia et al., 2001), a view supported by morphological analysis (Bräuer, 1994; Rightmire, 1990, 1994; Wu et al., 2005).

The traditional view of the migration of African *H. erectus* into Asia sometime around 1 Ma has been challenged by the discovery of fossil remains, purportedly representing *H. erectus*, at the site of Dmanisi, Georgia. The collection of cranial and postcranial material recovered from the site (including four relatively complete crania), found in context with faunal material and Oldowan-type tools, has been dated to between 1.8 and 1.1 Ma, with stratigraphic and faunal analysis supporting the older end of these dates (Gabunia et al., 2000, 2001).

This early date for the Dmanisi specimens, in addition to both their 'primitive' anatomy and the absence of any hand axes from this context (suggesting an Oldowan-like, pre-Acheulean

industry), indicates a much earlier dispersal of *H. erectus* from Africa than previously considered. Definitions of *H. erectus* have also been challenged by the Dmanisi material. The four fossil skulls show very small cranial capacities, ranging between 600 cm³ for specimen D 2700 and 775 cm³ for specimen D 2280 (Gabunia et al., 2000; Vekua et al., 2002), which aligns them more closely with *H. habilis* than with *H. erectus* (Rightmire et al., 2006), which has a mean cranial capacity (for both African and Asian specimens) of 902 cm³ (Cartmill and Smith, 2009). The body size of the Dmanisi individuals, estimated from postcranial measurements, has also been found to fall within the range seen in *H. habilis*, and the degree of humeral torsion (curvature in the shape of the upper arm humerus bone) is similar to that seen in *Australopithecus* and *H. floresiensis* (Lordkipanidze et al., 2007).

Other aspects of the skull and face anatomy of the Dmanisi sample appear to share characteristics more diagnostic of *H. erectus*, for example, the presence of a 'bulge' at the bregma (bregma eminence), flexion in the occipital bone, and a thickening of the bone along the sagittal suture of the parietal bones (sagittal keeling; see Figure 2; Rightmire et al., 2006). The general limb morphology and proportions of the Dmanisi individuals also appear to be more like those of *H. erectus*, being similar to the modern human pattern (Lordkipanidze et al., 2007).

The discovery of a mandible (specimen D 2600) in 2000, with its large size and general morphology differentiating it from other Dmanisi and *H. erectus* material, has led some to designate D 2600 as belonging to a new species, named as *H. georgicus* (Gabunia et al., 2002). This taxonomic assignment has not been well supported to date, with some researchers suggesting that the morphological variation seen at Dmanisi can be incorporated within existing descriptions of *H. erectus* (or into a subspecies of *H. erectus*; Rightmire et al., 2006; Vekua et al., 2002). It is clear that the Dmanisi group has a

Figure 2 Osteological landmarks of the human skull, as seen in (a) frontal view, (b) lateral view, and (c) superior view.

Figure 2 (Continued)

morphological mosaic unlike other contemporaneous species. Although some of these morphological features can be interpreted as symplesiomorphies (i.e., ancestral traits which are shared by two or more groups), there are also traits which appear unique to this group (Rightmire et al., 2006). Taken in combination with their age and location, this population can be interpreted as an early stage in the evolution of *H. erectus*, who left Africa before the emergence of *H. erectus* (sensu stricto; e.g., Rightmire et al., 2006; Vekua et al., 2002).

The 'Transitional' Hominins

The appearance of *H. erectus* in the fossil record around 1.8Ma and the subsequent appearance of *H. sapiens* (see

'The Appearance of *H. sapiens*') can be considered watersheds in the evolution of the human genus. Between these species, however, are found a number of 'transitional' hominins, who are crucial to the understanding of hominin evolution. The most well known (and perhaps least 'transitional') of these hominins are the Neanderthals (*H. neanderthalensis*). Less well understood are their African precursors, *H. heidelbergensis* and *H. antecessor*.

The name *H. heidelbergensis* was first assigned to a mandible discovered in the early 1900s in a quarry in the village of Mauer, near Heidelberg, Germany. The species definition, however, is based upon more complete cranial material from sites across Europe and Africa. Dating of these sites ranges between 600 and 400 ka which, in tandem with genetic evidence (e.g., Krings et al., 1997), support the notion that

H. heidelbergensis is a likely common ancestor of both *H. neanderthalensis* and *H. sapiens*. This is further supported by the anatomy of *H. heidelbergensis*, which can be considered 'transitional' between that of *H. erectus* and *H. neanderthalensis*.

Certain features of the cranium, such as a low frontal bone, large supraorbital torus (brow ridge), thick cranial vault walls, a raised and thickened ridge on the parietal bones (angular torus) and a lack of mental eminence (chin) are similar to those seen in *H. erectus* (see [Figure 2](#)). Other features, however, like the division of the supraorbital torus into medial (toward the midline of the body) and lateral (away from the midline) sections, the vertical (rather than sloping) margin of the nose, an incisive canal which runs vertically through the roof of the mouth, the general cranial base morphology, and a cranial capacity of around 1250 cm³ are more reminiscent of later *Homo* ([Rightmire, 2008](#)).

It can be seen, therefore, that it is the combination of these more primitive and more derived features that define *H. heidelbergensis* ([Rightmire, 1998](#)). It is precisely this 'transitional' morphology that can make it difficult to determine which specimens should be attributed to *H. heidelbergensis*, which has led to the species often being used as an umbrella term for individuals who are difficult to place elsewhere ([Bae, 2010](#); [Klein, 2009](#)). This has particularly been the case in the Asian fossil record, where taxonomic uncertainty has led to a number of 'transitional' hominins being assigned to *H. heidelbergensis* if they are not clearly *H. erectus* or 'archaic' *H. sapiens* ([Groves and Lahr, 1994](#); [Lahr, 1996](#); [Stringer, 2002](#)).

H. antecessor has been identified as an earlier potential common ancestor of modern humans and Neanderthals ([Bermúdez de Castro et al., 1997](#); [Carbonell et al., 2008](#)). This species is represented primarily by material found at the prolific Sierra de Atapuerca site of Gran Dolina (TD6 level) and Sima del Elefante (TD9 level) in Northern Spain and dated at around 780 ka (for TD6) ([Carbonell et al., 1995](#); [Parés and Pérez González, 1995](#)) and 1.2 Ma for TD9 ([Carbonell et al., 2008](#)). In this chronology, *H. antecessor* gave rise to both *H. heidelbergensis* in Europe (and ultimately Neanderthals) and to another species in Africa (potentially *H. rhodesiensis* or *H. helmei*) which was the forerunner of *H. sapiens*.

H. antecessor is known from a relatively large sample of cranial (see [Bermúdez de Castro et al., 1997](#); [Carbonell et al., 1995, 2008](#)) and postcranial (see [Carretero et al., 1999](#); [Lorenzo et al., 1999](#)) material. Some traits identified by Bermúdez de Castro and coauthors, such as a 'modern' mid-facial morphology with canine fossa (a depression in the facial bone above the canine teeth) align the specimens with later *H. sapiens*, whereas many aspects of the dental morphology can be considered more akin to the primitive condition exhibited by *H. erectus*/*H. ergaster*. This material is both fragmentary, however, and derived predominantly from subadult and juvenile individuals ([Cartmill and Smith, 2009](#)). This makes comparisons between this material and other specimens of adult status problematic (e.g., the calvaria from Ceprano, Italy). The taxonomic status of *H. antecessor* has been questioned ([Stringer, 2002](#)). It is problematic because it is known primarily from only one site (but see [Manzi et al. \(2001\)](#) for a description of the calvaria from Ceprano, and [Gilbert et al. \(2003\)](#) for a critique). Recently, lithic and faunal evidence from the site of Happisburgh in Norfolk, England has been

dated to at least 780 ka, but perhaps as old as 1 Ma ([Parfitt et al., 2010](#)). While no skeletal remains have been found at Happisburgh, it can be inferred that the site represents the activities of *H. antecessor*, the only hominin so far identified in Europe during this period.

Until such time as more, preferably adult, skeletal material is found that can be reliably dated and attributed to *H. antecessor*, it will remain difficult to understand the true range of variation in this species and its anatomical relationship with both *H. erectus* and *H. heidelbergensis*/*H. neanderthalensis*. This is necessary to determine the validity of *H. antecessor* as a species and its place in the fossil record as potentially the last common ancestor of Neanderthals and *H. sapiens*.

The Neanderthals are perhaps the best known of all the extinct hominin relatives, but in many ways they remain enigmatic. The history of the discovery and understanding of the species is also the story of the paleoanthropological discipline. Neanderthals have become such a part of popular human culture that their name is now used as a euphemism for primitive or uncivilized behavior. Increasingly, however, it is found that there was little in their behavior that separated them from *H. sapiens*. This understanding comes from the fossil and lithic record attributed to the Neanderthals, which is more extensive than for any other hominin species, with the unique addition of preserved DNA for some individuals. Yet despite this seeming abundance of data, there are still a large number of questions regarding their life history that remain unanswered, particularly regarding the 'modernity' of their behavior, the degree of interaction with *H. sapiens* in Europe, and the nature of their extinction.

The first Neanderthal specimen was found in 1830 in Gibraltar, although it was not recognized as such until much later. The first specimen recognized as Neanderthal was discovered in 1856 in the Neander Valley, Germany. The 'transitional' nature of preceding species like *H. heidelbergensis* make it difficult to pinpoint the exact FAD and LAD of *H. neanderthalensis*, but it is likely to be around 200 and 30 ka, respectively ([Wood and Lonergan, 2008](#); see [Figure 1](#)).

During their tenure in Europe, the Neanderthals appear to have expanded through most of the continent. There is lithic and skeletal evidence for their expansion into modern-day Israel (the sites of Skhul and Qafzeh) and Siberia (Okladnikov) to the East and into Northern Africa (the sites of Jebel Irhoud in Morocco and Haua Fteah in Libya) to the South. Lithic evidence should be interpreted with caution in the absence of associated Neanderthal skeletal remains, however, as Mousterian tools (the stone tool industry primarily associated with Neanderthals) in these Middle Eastern and African contexts have also been found with skeletal material believed to be *H. sapiens* ([Cartmill and Smith, 2009](#)).

In general terms, the cranial anatomy of Neanderthals can be distinguished from that of *H. sapiens* through examination of the cranial vault, which is much lower, longer, and wider than in *H. sapiens*, giving it a distinctive oval shape ([Hublin, 1980](#)). In addition, many European Neanderthals can be distinguished by the presence of an occipital 'bun,' a protrusion at the back of the skull ([Cartmill and Smith, 2009](#)). Interestingly, it has been found that Neanderthals had a unique inner ear bony labyrinth morphology, although the reasons for this are unclear ([Spoor et al., 2003](#)). Neanderthals are also known for

having significant midfacial prognathism (forward projection of the face), a broad supraorbital torus (brow ridges), a wide nasal aperture (nasal cavity), and a retromolar space (a gap between the last molars and the ascending arm of the jaw bone) (although this feature does not appear to be unique to Neanderthals, e.g., Trinkaus et al., 2003; see Figure 2). Certain aspects of the Neanderthal face are considered to be adaptations to living in cold environments, for example, the internal morphology of the nasal aperture (e.g., Churchill, 1998). This association has recently been challenged on the grounds that Neanderthal nasal sinus morphology does not differ significantly from *H. sapiens* when scaled for size. Alternative explanations for the shape of the Neanderthal face, such as biomechanical adaptation to masticatory stress and genetic drift have been proposed (Rae et al., 2011).

More support for cold adaptation can be found in Neanderthal postcranial morphology, particularly in their limb bone proportions. A short lower arm to upper arm ratio suggests conformation to Allen's rule, which states that animals living in cold environments develop shortened forelimbs in order to reduce their surface-to-volume ratio and therefore their heat loss (Holliday, 1997; Pearson, 2000; Ruff, 2002). Neanderthals are also known to have broad thoraxes (chest), which is interpreted as following Bergmann's rule, which is similar to Allen's rule in stating that increasing body mass reduces the surface-to-volume ratio and further conserving heat. This large thorax would also facilitate increased lung capacity which would allow Neanderthals to better deal with activity in a cold climate (Churchill, 2006). In addition, the Neanderthal skeleton is extremely robust in the size and shape of the long bones, with developed sites of muscle attachment on the bone, suggesting that the Neanderthals lived in a challenging physical environment (Pearson et al., 2006).

The discovery of ancient DNA in Neanderthal bones was a pivotal moment in the understanding of hominin evolution (Krings et al., 1997). Since that time, what has been learnt about Neanderthal genetics has proved difficult to interpret and has challenged our understanding of population genetics. It was originally believed that there was no genetic admixture between Neanderthal and contemporary modern human populations in Europe, suggesting little or no gene flow between the groups (e.g., Stringer and Andrews, 1988). More recently, this picture has been challenged, with analyses indicating that in fact as much as 4% of the modern human genome of populations outside of Africa is shared with that of Neanderthals. To obtain this level of shared variation suggests a high level of gene flow between the groups, and a level of interbreeding far in excess of what was previously assumed (Green et al., 2010; Plagnol and Wall, 2006).

This picture of Neanderthal and *H. sapiens* interaction during the Paleolithic has been further complicated by recent genetic evidence from Denisova, Siberia, which suggests that there was another, hitherto unknown, species of hominin living in this area of Eurasia between 50 and 30 ka (Reich et al., 2010). This species of hominin, known only as 'Denisovians,' is noteworthy for a number of reasons: their mitochondrial DNA (mtDNA – inherited solely through the maternal line) appears to diverge from the line leading to Neanderthals and *H. sapiens* approximately 1 Ma, twice the temporal distance posited for the mtDNA split between

Neanderthals and *H. sapiens*. The morphology of the associated skeletal remains shares no derived features that would reasonably link it to Neanderthals or *H. sapiens*, suggesting that this group continued to evolve in parallel after their split from the common Neanderthal/*H. sapiens* lineage. Reich and colleagues conclude that the Denisovian group sampled in their study share 4–6% of their genome with existing modern humans, specifically modern Melanesians. This finding clearly indicates that there was also a significant amount of gene flow between the Denisovians and *H. sapiens*, more than has been suggested for *H. sapiens* and Neanderthals, although the precise nature of this relationship and the identity of the Denisovians are currently unknown.

The Appearance of *H. sapiens*

The specter of *H. sapiens* has loomed over the discussions in the previous sections, used as a reference point for the 'modernity' or otherwise for all aspects of early *Homo* morphology and behavior. In order to be able to use modern *H. sapiens* as a lens through which to interpret other hominin species, however, one must first understand the history and development of this species, of which perhaps less is known than expected.

The understanding of the date of the first appearance of *H. sapiens* in the fossil record depends in part on how '*H. sapiens*' has been classified. Until relatively recently, it was thought that modern *H. sapiens* appeared across the Old World (i.e., Africa, Europe, and Asia) around 40 ka (e.g., Trinkaus and Smith, 1985; Wolpoff, 1980). This appearance was associated with the apparently abrupt emergence of 'modern' symbolic material culture, particularly prevalent in Europe. Since that time, this view has mostly given way to the notion that *H. sapiens* in fact first appeared in Africa as early as 200 ka. This has been supported by data on modern human genetic diversity, particularly mtDNA data, which indicate a common female ancestor of all modern groups, found in Africa ~200 ka, popularly known as 'mitochondrial Eve' (Cann et al., 1987; Ingman et al., 2000; Penny et al., 1995; Vigilant et al., 1991). The fossil record in Africa also lends support to this view, and suggests an even older FAD for *H. sapiens*, with the Florisbad (South Africa) skull being dated to around 260 ka (Grün et al., 1996). Other specimens from across Africa have been dated to more than 100 ka, from Herto (Ethiopia) at 160 ka (White et al., 2003), Jebel Irhoud (Morocco) at between 190 and 130 ka (Grün and Stringer, 1991), and Klasies River Mouth (South Africa) at about 100 ka (Rightmire and Deacon, 1991). It can be problematic to date sites of this age, which often provide only fragmentary skeletal remains, but the wealth of data that so far exists, both genetic and skeletal, supports the early appearance of *H. sapiens* in Africa.

This older date for the origins of *H. sapiens* has led to the inclusion of 'archaic' human specimens within the *H. sapiens* hypodigm (all of the fossil material of this species available for study). This has led the species to become extremely broad (when modern human variation is included), making a morphological definition of *H. sapiens* particularly challenging (Stringer, 2002). While there appears to be no formal definition of the morphology of *H. sapiens* (Schwartz and Tattersall, 2010), the species can be distinguished from its predecessors

by the presence of a two-part brow ridge with a glabellar 'butterfly' (the space in between the eyebrows and above the nose, which can protrude to resemble a butterfly) and a clear 'chin' (Schwartz and Tattersall, 2010). To this very short list can also potentially be added a number of other cranial features related to the morphology of the ectotympanic bone (structure within the middle ear that supports the eardrum), the styloid process of the temporal bone (pointed bone below the ear which anchors tongue and larynx muscles), occipital plane (outer surface of the occipital bone where the *occipitalis* muscle attaches), interdigitation (interlocking) of the cranial sutures (joints between cranial bones), the petrous (stone-like) part of the temporal bone (petrosal), subarcuate fossa (depression on the inner surface of the petrosal for the subarcuate artery), and inferior orbital plane (the inner surface of the eye orbit that is part of the maxilla (upper jaw); see Figure 2; Schwartz and Tattersall, 2010). More 'traditional' modern human traits, such as a high cranial vault with low frontal angle, a projecting mastoid process (protrusion of the temporal bone behind the ear, which is a point of attachment for several muscles), a canine fossa, an orthognathic face (i.e., located under the brain case) and absence of a retromolar space show a lot of variability in archaic and modern *Homo* and therefore highlight the difficulty in identifying those traits which are unique to *H. sapiens* but also shared by all members of the species (both archaic and modern; Figure 2) (Cartmill and Smith, 2009).

While an early origin of *H. sapiens* in Africa appears indisputable, the first appearance of 'modern' human material culture continues to be debated, due to its seemingly abrupt appearance in Europe around 40 ka. This symbolic material culture, in the form of rock art, carvings, and personal ornaments, has been assigned to the Aurignacian technological complex. The Aurignacian derives its name from the site of Aurignac in France, where the first stone tools assigned to this culture were found. This industry differs from earlier stone tool technologies (e.g., the Mousterian, also centered in Europe) by displaying a greater range of tool types, types which can be considered more 'finely crafted,' and the inclusion of standardized stone tools (Cartmill and Smith, 2009, p. 414). The abruptness of the appearance of the Aurignacian culture, the increased levels of symbolism relative to earlier technologies, and the association with modern *H. sapiens* archaeological contexts led to the period from 40 ka onward to be referred to as the 'Upper Paleolithic Revolution' (e.g., Bar-Yosef, 2002).

The notion of a European cultural 'revolution' was once prevalent in the understanding of modern human origins, but has been challenged on a number of fronts. The 'Eurocentric' nature of the 'Upper Paleolithic Revolution,' with its focus on a European origin for cultural modernity has been criticized by some (e.g., McBready and Brooks, 2000) for overlooking evidence for cultural sophistication in the African archaeological record dating back to 100 ka and developing complexity over time. For example, perforated shell beads and red ochre engraved with geometric patterns, found in the Blombos Caves in South Africa, have been dated to 75 ka and represent some of the earliest evidence for personal adornment and abstract image creation (d'Errico et al., 2005; Henshilwood et al., 2002).

Another area of debate has been the mechanism by which *H. sapiens* came to be so widely dispersed. Currently, the most

widely held viewpoint regarding the dispersal of humans through the Old World is the 'Out of Africa hypothesis' (or Recent African Origin hypothesis; e.g., Stringer and Andrews, 1988; Stringer et al., 1984). This states that *H. sapiens* evolved exclusively within Africa between 200 and 100 ka and that all humans alive today ultimately descend from these individuals, with the groups who left Africa replacing the last remnants of *H. erectus* in eastern Asia and Neanderthals in Europe. An opposing view, known as the 'multiregional hypothesis' (e.g., Wolpoff et al., 1984, 1988) proposes the concept of regional continuity, with *H. erectus* leaving Africa and evolving into *H. sapiens* evolving *in situ* across the world. This hypothesis sees the species definition of *H. sapiens* expanded to include species such as *H. erectus* and *H. neanderthalensis* and that a variety of factors such as local adaptation, interbreeding, genetic selection and drift resulted in local evolution that converged on the regional variation seen in *H. sapiens* today. An extreme interpretation of the Out of Africa hypothesis does not allow for any interbreeding or gene flow between *H. sapiens* and the populations they replaced. This view has been challenged by genetic analyses which suggest at least a certain amount of admixture between *H. sapiens* and Neanderthals (Green et al., 2010; Plagnol and Wall, 2006) and therefore the true story of evolution outside Africa is likely to be a less extreme form of the Out of Africa hypothesis, where some amount of gene flow took place between species.

What is becoming increasingly clear, particularly in light of the increasing amount of ancient DNA evidence that is becoming available, is that the story of *H. sapiens* migration across the Old World (but also into the New World) is incredibly complex. Recent DNA analysis of hominin material from Denisova, Siberia (Reich et al., 2010) has shown that archaeological evidence alone will not be able to explain everything that is needed to be known about the history of human expansion. A more comprehensive view of modern and ancient human population genetics, in combination with the rich anatomical and archaeological records from these periods, is ultimately the best hope for understanding the true nature of the human species' history and development.

It has long been assumed that, following the extinction of *H. erectus* in Asia and *H. neanderthalensis* in Europe by 30 ka (Wood and Lonergan, 2008), *H. sapiens* was left as the only surviving member of the genus *Homo*. This accepted picture was turned on its head with the discovery of skeletal and lithic material dating to between 95 and 18 ka on the Indonesian island of Flores (Brown et al., 2004; Morwood et al., 2005). What was revolutionary about these finds was the distinctive, and unexpected, morphology of the Flores individuals, which appeared to be a combination of primitive (e.g., small cranial capacity, wrist morphology) and more modern (e.g., obligate bipedalism, reduced dentition size and facial prognathism) traits which are unique to these individuals (Brown et al., 2004). The Flores individuals (and the LB1 holotype in particular) also display some unexpected traits, such as a very short stature and unusual limb proportions, represented in LB1 having very long feet relative to its leg length (Jungers et al., 2009).

Such was the uniqueness of the skeletal remains that they were assigned to a new species, *H. floresiensis*. Unfortunately, the preservation of DNA material in the *H. floresiensis* bones was poor, making phylogenetic analysis impossible. The

morphology of *H. floresiensis*, in combination with what are considered relatively advanced stone tools (Morwood et al., 2005), makes an understanding of the relationship of this species to other hominin species challenging. Fierce, and often acrimonious, debate has raged between researchers since the Flores material was first published. A range of species assignments have been made, but they can be split into two broad groups: those who believe that *H. floresiensis* is a derived descendent of early *Homo* and those who believe that the Flores individuals are pathological specimens of modern *H. sapiens*.

Those who believe that *H. floresiensis* is a new species derived from early *Homo* base their view on the primitive morphology. The morphology of the wrist and many aspects of the crania have suggested to researchers that the most likely ancestral candidate is *H. erectus* (Wood and Lonergan, 2008). If this is the case, this allows one to draw certain conclusions about the technological sophistication of the species that first arrived on the island. Even at the lowest sea levels, the island of Flores would have been separated from the nearest land mass by about 20 km of water; therefore reaching Flores would have involved a significant water crossing. While it is known that some form of water-crossing technology was necessary for *Homo* to reach the Australian landmass, around 60 ka (Thorne et al., 1999), the discoveries on Flores suggest a much earlier development of this behavior.

Some researchers have suggested an even more ancient origin for *H. floresiensis*, believing them to have descended possibly from *Australopithecus* or another early hominin species (Argue et al., 2006; Falk et al., 2005; Jungers et al., 2009). While further data are necessary to determine the veracity of this hypothesis, it forces one to consider the potential technological sophistication and capabilities of the earliest hominins.

Critics of the *H. floresiensis* concept believe that the material on Flores represents pathological examples of dwarf modern *H. sapiens*. The most commonly proposed idea is that the LB1 cranium is from an individual suffering from a form of microcephaly, which results from compromised neural development and leads to a small brain size relative to face size (Henneberg and Thorne, 2004; Jacob et al., 2006; Martin et al., 2006; Weber et al., 2005). Modern humans with this condition often suffer from cognitive impairments and a certain amount of dwarfism.

This view has been strongly criticized, on the grounds that LB1's suite of features is primitive and cannot be explained by any developmental disorder (Argue et al., 2006; Falk et al., 2005, 2006, 2007; Larson et al., 2007; Tocheri et al., 2007). Another blow to this hypothesis came when additional skulls were found in the Liang Bua excavations (e.g., LB6) – all exhibiting small cranial capacity. Microcephaly is a rare genetic abnormality in humans, so the odds that multiple individuals from a small group all exhibited this same genetic disorder seem quite small. Undeterred by this, other possible disorders have been suggested to explain the morphology of *H. floresiensis*, including Laron Syndrome (Hershkovitz et al., 2007) and myxoedematous endemic cretinism (Obendorf et al., 2008), again strongly refuted (Falk et al., 2009).

With the data currently available, the most parsimonious explanation for the Flores material seems to be that they represent some descendent of an earlier species of *Homo* that underwent island dwarfism once reaching Flores. Such is the unique and incomparable nature of these individuals; however, it is unlikely that the disagreements will be settled until

more undisputed material is found. Whatever future evidence is obtained, it will no doubt shed light on one of the most intriguing issues in paleoanthropology and force the reevaluation of the key aspects of hominin evolution such as brain expansion and cognitive organization and complexity.

Conclusions

The complexity and scope of human evolution cannot be done justice in so few words, but what this article has attempted to show is that, while the human genus has been subject to the same selection pressures as other animals, it is how hominins have responded to those pressures that has ultimately made the human genus distinct. It is the unique behavioral plasticity of *Homo* that has allowed hominins to respond to environmental pressures through the development of technologies. This encouraged a more diverse exploitation of resources, and ultimately led to the development of symbolic material culture. Significant changes in the locomotor repertoire of humans has facilitated an expansion of the geographic range of the human genus that is unknown in any other primate, thus taking *Homo* into new and challenging environments, further promoting adaptability of human beings. What processes led to the behavioral flexibility and adaptability of humans are unclear, and given the somewhat incomplete fossil record, it is understandable that passionate debate on these questions continues and contentious issues remain. Ongoing research will enable more pieces to be added to this fascinating evolutionary jigsaw and increasingly shed more light on the enigmatic origins of this unique primate genus.

Neanderthal Demise

W Davies, University of Southampton, Southampton, UK

This article is reproduced from the previous edition, volume 1, pp. 135–145, © 2007, Elsevier B.V.

Introduction

The extinction of the Neanderthals (*Homo neanderthalensis*), and the arrival of modern humans (*Homo sapiens*) in Europe between 45 and 30 thousand years ago ('ka BP') is one of the most hotly debated topics in Paleolithic archaeology and paleoanthropology. Why? What is the evolutionary and behavioral importance of this transition?

Most researchers in this period of human evolution incline more toward a single-origin model for the evolution of modern humans, with a subsequent expansion out of Africa into Asia, Greater Australasia, and Europe, ultimately replacing the Neanderthals in the latter subcontinent (e.g., Mellars (1989), Stringer (1989), and d'Errico et al. (1998)). However, a substantial minority of researchers believe the multiregional origin hypothesis to be more appropriate, with modern humans evolving independently in many regions of the Old World, yet sufficiently connected to each other to facilitate the exchange of genes, allowing *Homo sapiens* to develop at a global scale as a single species for the last two million years (e.g., Wolpoff and Caspari (1997)). The models have distinctive temporal and spatial scales: single-origin models tend to think in terms of speciation locations (with subsequent dispersals) and events, while multiregional ones think in terms of global population interactions and broad (sympatric) speciation processes. Both models can conceive of population extinctions and replacements, although these are more geographically restricted if one is a multiregionalist (Wolpoff and Caspari, 1997). Because this author has difficulties in believing that multiregionalism can operate at the large spatio-temporal scales proposed by its adherents, the single-origin ('Out-of-Africa 2') model will be given stronger preference for much of the discussion in this article.

Species Definitions

Neanderthals

Although specimens had been discovered in 1830 (Engis, Belgium) and 1848 (Gibraltar), it was not until a third one was recovered from the Neander valley ('Neanderthal') in Germany in 1856, that species-specific traits were identified (King, 1864) and a new hominid species was classified, indeed the first human species to be distinguished since the publication of Darwin's *On the Origin of Species* in 1859. Neanderthals were notable for their stocky build, but it is their cranial characteristics that are the most diagnostic: a protruding mid-facial region, emphasized by the lack of a distinct chin, and thick, well-developed brow-ridges over the eyes, which grade backward into a weakly developed forehead. Seen from above, it is as if someone has taken the modern human skull shape we are used to, and stretched it longitudinally. Nevertheless, the

cranial capacity (brain size) of Neanderthals is not notably different from that of modern humans, averaging some 1400 cc. Perhaps because of our simplistic views of what characterized the climatic conditions of Ice Ages, it has often been claimed that Neanderthals were adapted to exceptionally cold ('hyperarctic') conditions (e.g., Holliday (1997)). However, if Neanderthals preferred cold conditions, then how can we explain their presence in the Near East or Iberia: two regions not known for their climatic affinity with the Arctic (see Aiello and Wheeler (2003))?

Two enlightenment-derived perceptions of Neanderthals have tended to dominate, both crystallized from mythology: men-as-monsters and men-as-gods. An example of the former is to see Neanderthals as something akin to Shakespeare's Caliban: a distillation of all that is monstrous in humans; an example of the latter is surely the concept of the 'Noble Savage.' Presumably owing to their 'coarse' physical features, Neanderthals have tended to be seen as more monstrous than noble, but recently the pendulum has begun to swing the other way (e.g., d'Errico et al. (1998)). It will be seen, however, that such Cartesian dualities are difficult to test or falsify against evidence that is largely ambiguous.

The origins and extent of Neanderthal symbolic behavior is one of the most problematic debates in Paleolithic archaeology, and is dependent upon the vagaries and chronological precision of the extant archaeological record. It was frequently thought that Neanderthals were incapable of complex spoken language, not just on the grounds of mental ability but also of physical capability. The claims of, among others, Lieberman (1989), that the configuration and morphology of the Neanderthal vocal tract ensured that they could not vocalize like ourselves, have been largely discredited by the morphological similarity of the hyoid bone from a Near Eastern Neanderthal (at Kebara, Israel) to those of modern humans (Arensburg, 1989).

Modern Humans

Homo sapiens are one of the most poorly defined species in the animal kingdom, with relatively few diagnostic physiological features. In comparison to Neanderthals, we have a much flatter mid-facial region, with a pronounced chin and steep forehead (with weak brow-ridges). The elongated body shapes of many modern humans, today and in the past, are congruent with our proposed origins in the tropics (of Africa). Behaviorally, modern humans have been defined by the universal use of complex spoken language, with a strong capacity for abstract and metaphorical thought (e.g., Mellars (1989)). In recent decades, this 'symbolism' has leapt to the forefront of the debate on the origins of modern humans, with positions on the assembly of the 'modern human behavioral package' being dichotomized as either 'long chronology' (the gradual accretion of modern characteristics) or 'short chronology' (a sudden

explosion of unprecedented modern behavior) (e.g., McBrearty and Brooks (2000) vs. Klein (1995)).

Neanderthal and modern human technologies

Tables 1 and 2 give brief summaries of the archaeological groupings we shall consider, and their skeletal associations (where known). Some terms, especially in Table 1, need further explanation, and the archaeological groupings, henceforth called technocomplexes, need to be set into their spatial and temporal contexts. A technocomplex (following Clarke (1968)) is a group of cultures that share a range of common characteristics, but differ – perhaps by region or time period – in the presence/absence of specific artifact types. The term ‘culture,’ while widely used, is seldom defined, and carries much interpretative baggage. Hence, technocomplex will be preferred here; in any case, its broad spatio-temporal scaling probably better matches most of the archaeological groupings we are discussing.

The technocomplexes listed in Tables 1 and 2 are not exhaustive, but represent a fair selection of those thought to be significant, and/or associated with human remains. They can be grouped into two larger conceptual units, defined largely by how the stone tools were made. Middle Paleolithic assemblages (‘Mousterian,’ if they contain Mousterian points) are generally flake based, that is, their ‘blanks’ for tool production are generally wide and relatively short, and were frequently obtained by a knapping technique called ‘Levallois.’ Classic Levallois entails the careful preparation of a flat stone nodule by first regularizing its entire margin through the removal of overlapping flakes from one (normally the upper) surface, making the core ovoid in shape. The flat surfaces created by these peripheral flake scars are then used as a platform to remove overlapping flakes centripetally from the whole upper surface of the core, creating a ‘tortoise-shell’ gently domed surface that will yield an oval, gently domed flake when struck from one end. Control of the convexity and regularity of this surface is critical. Variants of this Levallois technique exist, producing triangular flakes (‘Levallois points’) and blades (blanks whose lengths are at least twice their widths): the different shapes are created by changes in the orientation of the upper surface’s preparatory removals rather than in the convexity of the surface. Upper Paleolithic assemblages, conversely, frequently used blades produced from prismatic – often conical – cores: not only are these blades at least twice as long as they are wide, but they also carry parallel scars of blades previously removed from the core, whose scar edges form longitudinal ridges on their upper (‘dorsal’) surfaces, typically giving them a trapezoidal cross section. Bladelets are small blades, generally less than 12 mm wide, and sometimes attaining lengths of 50–60 mm (Hassan, 1972).

Having generalized that Middle Paleolithic (flake-based) technologies are associated with Neanderthals, and Upper Paleolithic (blade-based) ones with modern humans, we should be aware that there are important exceptions. In the Levant of southwest Asia, modern human remains are associated with ‘Tabūn C’-type Mousterian assemblages at sites such as Qafzeh and Skhūl at about 100–90 cal ka BP. Unlike thermoluminescence (TL), optically stimulated luminescence (OSL), uranium series, and electron-spin resonance (ESR), radiocarbon dates need to be converted into calendar years (normally designated

as ‘cal BP’). Only recently, however, have calibration curves been applied to radiocarbon dates in our study period (van Andel et al. (2003), etc.), and readers should be aware that there is not yet any universally accepted calibration curve, and probably never will be, as such curves tend to be revised regularly to accommodate new data. The calibrated radiocarbon dates given here (using the CalPal 2005 default curve; Weninger and Jöris (2005) – <http://www.calpal.de>) should be treated broadly and with a degree of caution, but they have the advantage of giving more accurate age estimates than uncalibrated radiocarbon dates, and they allow comparison with the other, aforementioned dating techniques. There appears to be little in their behavioral repertoires to distinguish them from the contemporary and subsequent Neanderthals in that area (Bar-Yosef (1993); Mellars (1989): p. 354). At about the same time in northern Europe, Neanderthals appear to be making blades in exactly the same way as would become the norm in the Upper Paleolithic, before apparently reverting to more ‘typical’ flake-based technologies (e.g., Révillion and Tuffreau (1994)). Therefore, our debate should be less about technological capacity than about preferred technological modes, and about the frequencies of particular core-reduction strategies employed to produce tool blanks.

In most parts of western Eurasia, the Middle Paleolithic technocomplexes listed in Table 1 have disappeared by ca. 35 cal ka BP, although some persisted, particularly in southern Iberia, Croatia, the Crimea, and the Caucasus, until perhaps 30 cal ka BP (e.g., van Andel et al. (2003)). Outside these apparently isolated ‘pockets’ of survival, it becomes much more difficult to identify surviving Neanderthals. The Châtelperronian of France (and perhaps northern Iberia) is the only Upper Paleolithic technocomplex attributed to Neanderthals with any confidence, lasting between ca. 43 and 30 cal ka BP. In particular, this association is based upon the finds from two sites in northern central France: Roche à Pierrot (St.-Césaire) and Grotte du Renne (Arcy-sur-Cure) (e.g., Hublin et al. (1996)). Thus, toward the end of their existence we can see Neanderthals’ behavior changing rapidly in some environments, and utilizing, for apparently the first time, bone and ivory to produce not just tools (awls, etc.) but also elements of personal adornment (beads, pendants, etc.), apparently providing evidence for the application of social meaning to particular artifacts by this species. The big debate in archaeology at the moment is whether this apparent increase in symbolic activity among some Neanderthals was the result of socially internal developmental trajectories, or the result of contact and social interactions with incoming modern human groups – with the behavior of both groups being changed (e.g., d’Errico et al. (1998)). Perhaps the deteriorating conditions in the northern part of the Neanderthal range in France required a change in their social and symbolic behavior: beads, etc., might have been needed to reinforce links between groups in adverse conditions. Certainly, there is little evidence of identifiable symbolic behavior in Neanderthals prior to the Châtelperronian; there are very few isolated and unique finds from some Middle Paleolithic sites, but nothing that can be compared stylistically at the intersite scale. Paradoxically, it seems that Neanderthals were adopting explicitly symbolic behavior (and thus hinting to many archaeologists at the capacity for modern human behavior) just at the time of their extinction (Mellars et al., 1999).

Table 1 Characteristics of selected western Eurasian archaeological technocomplexes at the transition between Neanderthals and modern humans

<i>Technocomplexes</i>			<i>Diagnostic characteristics</i>
Middle Paleolithic	SW Asia	Tabun C-type Mousterian	Squat, thin triangular flakes (Levallois points) are common. Succeeds the Tabun-C variant, and has higher quantities of more elongate Levallois points and retouched tools.
		Tabun B-type Mousterian	
	East Europe	Caucasian Mousterian	Several variants are present: 'para-Micoquian' in the north Caucasus. Typical Mousterian (Levallois <i>and</i> non-Levallois, sometimes with bifaces), (Levallois) Denticulate Mousterian on the NE Black Sea coast, and a Charentian Mousterian site with bifaces as well as sidescrapers.
		Crimean Mousterian	Several variants: the 'Ak-Kaya ('para-Micoquian') tradition,' with bifacial (foliate) knives and points, sidescrapers and some Charentian characteristics (e.g., slug-like highly retouched stone tools called 'limaces'), also encompasses the Kiik-Koba and Staroselian variants. Typical Mousterian assemblages (see below) are concentrated in the nearby Dnestr basin, and they are founded upon Levallois technology.
		East European Micoquian	Perhaps better called <i>Keilmessergruppen</i> , named after the characteristic large, bifacially retouched knife-like tool with an acute cutting edge on one margin. Also contains elongate bifaces with asymmetric cross sections (<i>Halbkeile</i>), small pointed bifaces (<i>Faüstel</i>) and foliate bifaces (<i>Faustkeilblätter</i>). Many of these bifacial forms were made on flat stone nodules; the Levallois technique is sometimes present.
	West Europe	Typical Mousterian	Relatively undifferentiated from other western European Mousterian variants, except that bifaces and backed knives are absent or very scarce. Contains sidescrapers (some of Quina type), Mousterian points, some denticulates and notches.
		Mousterian of Acheulean Tradition ("MTA")	Two phases: (1) MTA-A, with triangular and pointed ovate ('cordiform') bifaces and scarce backed knives, then (2) MTA-B, with less common, exclusively cordiform bifaces and numerous backed knives (some of which anticipate the Châtelperron knife in their morphology). Both phases also contain Mousterian points, sidescrapers, notches and denticulates.
		Charentian Mousterian	Two variants, in roughly chronological order: (1) Ferrassie type, with presence of the Levallois knapping technique and numerous Mousterian points, then (2) Quina type, whose prevalent 'salami-slice' knapping method ('slicing off' flakes from a sausage-shaped stone nodule) was primarily used to make thick, distinctively retouched sidescrapers. Both variants are dominated by sidescrapers (some with bifacially worked convex edges), with fewer notches, denticulates, burins, and endscrapers.
Upper Paleolithic	SW Asia	Denticulate Mousterian	Slightly more distinctive than the typical Mousterian, with high ($\leq 80\%$) levels of notches and denticulates, generally $\leq 10\%$ sidescrapers, scarce endscrapers, borers, and burins; other Mousterian tools are (near-)absent.
		Emiran	Mousterian-like assemblages, characterized by Levallois points carrying bifacial thinning on their bulbous (proximal) ends.
		Baradostian	Production of bladelets from carinated cores, and their transformation into Dufour bladelets and points resembling Font-Yves ones has led some to call it 'Zagros Aurignacian' (Olszewski and Dibble, 1994), but other elements, such as backed blades and 'retouched rods' are not so easy to fit within the Aurignacian.
		Ahmarian	Blade/bladelet dominated assemblages, with diagnostic 'chamfered' pieces, el-Wad points, backed blades/bladelets. Surviving symbolic activity is rare, and bone-working is limited.
	East Europe	Bohunician	Contains a mixture of Middle and Upper Paleolithic elements: sidescrapers, Mousterian points, and a few bifacial leafpoints in association with endscrapers (some Aurignacian-type) and

(Continued)

Table 1 (Continued)

	<i>Technocomplexes</i>	<i>Diagnostic characteristics</i>
West Europe	Szeletian	burins. Both (Upper Paleolithic) blade reduction and Levallois techniques were applied to the same cores. Defined by bifacial leafpoints, with endscrapers (a few Aurignacian type), sidescrapers, Mousterian points and pointed retouched blades; more flake orientated than the Bohunician.
	Jerzmanowician	Defined by laminar leafpoints retouched mainly on the bulbed end of one (the ventral) surface. Splintered pieces and some Mousterian tool types (no sidescrapers) also present.
	Lincombian	Characterized by 'blade-points' (a type of unifacial leafpoint: cf. Jerzmanowician), with some bifacial points. Otherwise very heterogeneous (mixed assemblages?), with Aurignacian tools sometimes present, e.g., <i>busqué</i> burins.
	Châtelperronian	Defined by the backed Châtelperron knife/point; associated with Mousterian-type tools (sidescrapers, etc.). A mixture of flake and blade-orientated strategies is present. Beads, pendants and some bone-working found in some northerly sites.
	Uluzzian	Defined by generally scarce small backed lunates, mostly on flake fragments, although apparently on blades in Greece; also Mousterian tools, splintered pieces, endscrapers, and some bone-working ("awls").
	Aurignacian	Characterized by osseous projectiles, notably the split-based antler point, but also simple-based/lozangic/Mladečc and biconical ones; lithic tools include Dufour bladelets, Font-Yves/Krems/el-Wad points, Vachons and <i>busqué</i> burins, nosed and carinated scrapers, and marginally retouched Aurignacian blades. Beads/pendants are common; some anthropomorphic and zoomorphic figurines.
	Gravettian	Defined by the Gravette point, associated variously with Noailles and Bassaler burins, <i>fléchettes</i> , Font-Robert points and Kostenki points. Prismatic blade(let) technologies are strongly present. Symbolic activity is especially characterized by the female 'Venus' figurines.

The other European early Upper Paleolithic technocomplexes that are often assumed to have been made by Neanderthals, by analogy with the 'transitional' characteristics of the Châtelperronian, are actually blank slates on which archaeologists can impose their prejudices. The Uluzzian, Szeletian, Jerzmanowician-Lincombian, and Bohunician have not yet yielded any (diagnostic) human remains, although this has not stopped them being attributed to Neanderthals (e.g., d'Errico et al. (1998)). The Levantine Emiran, perhaps dated to about 50 cal ka BP (or earlier), appears to have developed into the Ahmari in situ within the Levant (Marks and Volkman, 1983); the latter technocomplex was probably associated with modern humans, if the skeletal remains from the Lebanese site of Ksar 'Akil are representative and reliable (Ohnuma and Bergman, 1990). The Emiran has also been connected with the Bohunician of central Europe – they share a similar use of Levallois technology – and it has been postulated that both might have been made by modern humans, who dispersed from the Levant to Europe at around 45 cal ka BP (e.g., Tostevin (2003)). At present, it is difficult to test this hypothesis, although the Bohunician does seem to represent a technological break with the local Middle Paleolithic of central Europe. This is different from the western European situation, where the

Châtelperronian shares several characteristics with the MTA-B (Table 1), for example, backed knives/points, and probably was derived from it.

The pan-European Aurignacian and Gravettian technocomplexes have been extensively studied, and are presumed to be 'true' Upper Paleolithic entities. In addition to the working of bone, antler, and ivory (not just to produce awls), the use of bladelets in both was extensive, and is not really seen in preceding (Neanderthal) European technocomplexes (Bar-Yosef and Kuhn, 1999). Bladelets permit flexibility, in that they can be arrayed in a shaft in different combinations to perform different tasks; any component unit ('microlith') can be replaced easily if it breaks.

It has often been argued that the Aurignacian was carried out of the Levant into eastern Europe, and then continued to move westward (e.g., Mellars (1989)). However, the earliest Aurignacian-type assemblages appear to be eastern European, dated at about 43 cal ka BP, and slightly later Aurignacian assemblages have been found further east in the Levant, as well as further west in Germany, Franco-Cantabria, and Belgium. At face value, the relative lateness and restricted spatial distribution of Levantine Aurignacian sites might appear to contradict hypotheses arguing for a spread of modern humans

Table 2 Skeletal associations of archaeological technocomplexes in western Eurasia

^aAurignacian in the broad sense, including the 'Bachokirian' of eastern Europe.

out of Africa into Europe via the Levant, but it can easily be argued that what we know now as the 'Aurignacian' developed as people had to respond to different environmental conditions and spatial distributions of raw materials and resources. The Levantine Aurignacian might thus represent a back-migration of the European Aurignacian into the Near East. The Aurignacian seems to have been made by modern humans, as far as we can judge, although in contrast to the preceding Middle Paleolithic and succeeding Gravettian technocomplexes, it has tended to yield fragmentary associated human remains (e.g., [Henry-Gambier et al. \(2004\)](#)). Perhaps the desire to break up bodies was related to the apparent adaptations to high mobility shown by the Aurignacian. The Gravettian can be more confidently ascribed to modern humans, as whole human bodies were interred in identifiably symbolic burials. Some of the earliest modern human remains in Europe have no associated archaeology ([Table 3](#)): they are certainly contemporary with the Aurignacian, although we cannot be certain that they themselves were its authors.

How and why did Neanderthals become extinct?

We shall explore Neanderthal responses to changing climate in this section, which of course means we must consider elements of chronology and how they exploited food and other resources. Intercomparability of dating techniques is important, as it allows us to compare our results with the Greenland ice-core climate records (given in cal BP). Taking the dated sites we have at face value, it would appear that Neanderthals were most successful between 60 and 40 cal ka BP, which was the stable warm phase of (marine) oxygen isotope stage (OIS) 3, immediately after the cold maximum of OIS-4 (72–60 cal ka BP) ([van Andel et al. 2003](#)). After 40 cal ka BP, the climate began to cool, and by 30 cal ka BP Neanderthals appear to be extinct.

Naturally, the dating methods we use, and how we apply them, are crucial if we are to be confident in the chronology we have (see [Dating Techniques](#); [AMS Radiocarbon Dating](#); [U-Series Dating](#); [Thermoluminescence](#); [Electron Spin Resonance Dating](#)). Radiocarbon is still the main dating technique for our study period – owing to reasons of its affordability, the prevalence of organic remains at many archaeological sites, and its availability over more than 55 years – even though its reliability decreases beyond 30 ka BP and only a few laboratories produce reliable age estimates beyond 40 ka BP. 50 ka BP is essentially the limit of the method. Other dating methods, such as TL, OSL, uranium series, and ESR, are needed

to extend our (reliable) chronology further back in time, certainly beyond 30 ka BP.

If we believe that replacement of Neanderthals by modern humans occurred in Eurasia, then we have recourse to two competing hypotheses: either Neanderthals were outcompeted by modern humans (what one might call 'confrontational replacement'), or they had already become extinct before modern humans arrived in an area ('successional replacement'). To test these models, archaeologists have traditionally used two lines of chronological/associative evidence: the relative stratigraphic positions of assemblages attributed to both human species, and/or absolute dating of the latter. While relative stratigraphic positions can give us an idea of succession, or perhaps indicate contemporaneity if interstratification can be proved, they give no real sense of chronology: without absolute dating methods, we do not know the duration of each depositional (or erosional) phase represented by a geological layer. In addition, it is by no means evident that a geological layer is equivalent to a phase of human occupation at a given site. It is instead obvious that in many cases a geological layer contains the remnants of more than one occupation episode; taphonomic disturbance between levels is not necessarily the only explanation for wide age estimate ranges for a given layer. Obtaining direct dates on anthropogenic material, ideally diagnostic artifacts, is obviously the way to identify such occupational phases, but has only recently begun to be practiced.

Current evidence does not tend to support arguments of interstratification, with the claimed occurrences at the French sites of Roc de Combe and Le Pige being now generally attributed to taphonomic disturbance and redeposition of sediments (see [d'Errico et al. \(1998\)](#)). Nevertheless, a recent claim has been made for interstratification of Châtelperronian (assumed to be Neanderthal) and Aurignacian (modern human) levels at the French site of Châtelperron (see [Mellars et al. \(1999\)](#), p. 346). Notwithstanding the stratigraphic evidence, current absolute dates for both Neanderthal and modern human technocomplexes do overlap temporally at the regional scale, especially in western Europe (France and Iberia), between ca. 43–33 ka BP (ca. 47–38 cal ka BP).

Stratigraphic information, then, would suggest that Neanderthals almost always preceded modern humans at sites where technocomplexes from both species are found, while the absolute ages we have (including those from sites with technocomplexes attributed to just one species) suggest a broader contemporaneity. Both lines of evidence are actually telling us subtly different things: the stratigraphic evidence is telling us about the chronology of occupation in a site, and,

Table 3 Directly dated late Neanderthal remains and those of early modern humans in Europe between ca. 50 and 30 cal ka BP

	<i>Site/specimen</i>	<i>Lab. No.</i>	<i>Date (uncal BP)</i>	<i>Date (cal BP)</i>	<i>Comments</i>
Neanderthal	Mezmaiskaya: layer 3d	Ua-14512	29 195 ± 965	33 855 ± 1,318	A late Neanderthal from the Caucasus mountains.
	Vindija Cave: layer G1	OxA-8296	29 080 ± 400	34 180 ± 640	Both C14 dates (OxA-) are much younger than the 2 uranium series ones.
		**	51 000 ± 8000	51 000 ± 8000	
		**	46 000 ± 7000	46 000 ± 7000	
	Feldhöfer-kirche (Neandertal)	OxA-8295	28 020 ± 360	32 560 ± 728	Both dates are from the Neanderthal type-specimen(s).
		[ETH-??]	39 240 ± 670	43 468 ± 594	
Modern human	Banyoles: lake travertine (5 m depth) around mandible	[ETH-??]	39 900 ± 620	43 806 ± 564	A striking difference between the very young C14 date (UCLA-) and the uranium series one.
		**	45 000 ± 4000	45 000 ± 4000	
	Pestera cu Oase: mandible	UCLA-930	17 600 ± 1000	21 098 ± 1151	This site appears to have the earliest-known modern human in Europe; no associated archaeology however.
		OxA-11711	>35 200	N/A	
	Oblazowa: layer VIII: phalange	GrA-22810	34 290 + 970/-870	39 823 ± 1,301	
		OxA-4586	31 000 ± 550	36 110 ± 496	
	Mladeč: ulna & teeth	VERA-2736	26 330 ± 170	30 997 ± 130	Some associated (Aurignacian) artefacts, but the dates are quite variable: the ulna (VERA-2736) and the 'brown-colored collagen fraction' (VERA-3075) are notably younger than the other two dates (on teeth).
		VERA-3073	31 190 + 400/-390	36 263 ± 381	
		VERA-3074	31 320 + 410/-390	36 367 ± 382	
		VERA-3075	30 680 + 380/-360	35 873 ± 385	
		VERA-3076A	31 500 + 420/-400	36 512 ± 408	
		VERA-3076B	27 370 ± 230	31 646 ± 290	
	Grotte de Cussac, loc.1 : rib	Beta-156643	25 120 ± 120	30 103 ± 193	A Gravettian, not Aurignacian, age.
	Kent's Cavern: maxilla	OxA-1621	30 900 ± 900	36 065 ± 851	The earliest modern human in western Europe?
	Paviland (Goat's Hole)	OxA-1815	26 350 ± 550	30 896 ± 339	A Gravettian, not Aurignacian, age from a complete burial.
		OxA-8025	25 840 ± 280	30 684 ± 232	

Trinkaus E et al. (2003) *Proceedings of the National Academy of Sciences* 100: 11231–11236; Wild EM et al. (2005) *Nature* 435: 332–335; other references in Davies W (2001) Stage Three Project Archaeological Database: <http://www.esc.cam.ac.uk/oistage3/details/homepage.html>

when taken at the regional scale, is telling us something about how groups of each human species used their landscape and its resources. The absolute ages are telling us about when sites were occupied, and by incorporating ages from sites with, say, only Aurignacian remains (and none attributed to Neanderthals), we can plot the distributions of Neanderthals over time and space: at certain periods, were some areas 'Neanderthal' or 'modern human?' Any sites with interstratified Neanderthal and modern human archaeological assemblages would thus represent shifting boundaries between the two species.

The desire of d'Errico et al. (1998) to see Neanderthals never overlap with modern humans, based on site stratigraphic successions, favors independent invention by Neanderthals of blade technology and bone working without any influence (known as 'acculturation') by incoming modern humans. Having found new solutions to (new) problems, they then suffer the misfortune of local extinction. Acculturation is very much in the thoughts of those who favor a contemporaneous existence for both species prior to Neanderthal extinction, with social connections between Neanderthal and modern human groups catalyzing behavioral changes, either equally or unequally distributed between each species. At present, our data are not good enough to identify any possible acculturation in either direction between modern humans and Neanderthals, but a useful start to addressing this problem would be made if the bones of contention (diagnostic artifacts) were themselves dated, and the chronologies then compared directly.

Archaeologists like to identify boundaries in the Paleolithic world, and a major one that has arisen in the literature over the last 15 years has been the so-called 'Ebro frontier' (e.g., d'Errico et al. (1998)). It is claimed that modern humans were either unable or unwilling to disperse into the parts of Iberia south of the river Ebro until about 30 cal ka BP; until that time, the region remained a Neanderthal bastion. It is of course doubtful that a river could form a boundary to a species that had already dispersed over huge distances, and even reached Australia, and the frontier's proponents thus claim that it was ecological factors (notably the structure of habitats, and the resources available) that held the marauding moderns at bay. When the Mousterian sites in Iberia are plotted on the map, it is evident that the sites we have are concentrated around the margins of this peninsula: the central, upland Meseta region is more or less uninhabited, and perhaps it formed a 'buffer zone' between the largely modern human occupied north, and the late Neanderthals in the southerly coastal regions.

The oddity is that these last Neanderthals in southern Iberia were relatively conservative in behavioral terms: they did not make Châtelperronian assemblages, and continued with the Mousterian. Perhaps they could afford to behave in this fashion because environmental change in this region was lesser than elsewhere in western Europe; the tightly packed mosaic of different habitats ensuring that Neanderthal groups did not have to range too widely to obtain the resources they needed to

survive. Modern humans, in contrast, tended to range more widely, certainly in terms of acquiring stone raw materials for their tools, and to make greater use of these 'exotic' raw materials; they also obtained marine shells over long distances for use in personal adornment (see Mellars (1989), p. 361). However, in terms of animal species exploited, there are fewer clear-cut differences between the two human species: both tended to hunt medium-to-large mammals (reindeer, red deer, wild boar, horse, mammoth), although at some sites we can see that modern humans exploited an impressive range of animals, ranging from mammoths at one end of the scale to hares, fish, and birds at the other. Only in the last two decades or so have archaeologists begun to ask how Neanderthals and modern humans exploited the same food species, and whether their exploitation strategies show any clear differences (Stewart, 2004). It has been observed that Neanderthal skeletons show high levels of trauma and injury: probably their hunting methods led to frequent close-contact encounters with their prey, but in the absence of comparable early modern human remains, we cannot say if these injuries were unique to Neanderthals (Berger and Trinkaus, 1995). Nevertheless, we are still a long way from identifying seasonal differences in the occupation periods at sites: where Neanderthals and modern humans were at particular times of year is not a question we can yet answer.

As fine-grained mosaics of different habitats became increasingly rare in Europe after 37 cal ka BP, replaced by swathes of more homogeneous environments, Neanderthals would have found it more difficult to obtain the resources they needed and to move to surviving refuges. Fragmentation into small pockets of suitable habitats would render them much more susceptible to extinction, especially with modern humans 'playing cuckoo' in the interstitial areas they once inhabited. Whether or not modern humans had a significant behavioral advantage (they at least managed to survive the last cold maximum of the Ice Age at ca. 21 cal ka BP), they could have administered the fatal blow to Neanderthals simply because they were not restricted to Europe: waves of modern humans coming in to Europe could always replenish groups that had become extinct, whereas Neanderthals could never call upon reinforcements from outside Europe.

We stand today at the threshold of a new dating revolution in the transition from Neanderthals to modern humans: being able to date diagnostic organic artifacts, for example, the bone industries from some Châtelperronian sites, will allow us to state with more confidence whether they can be attributed to Neanderthal authorship or not. If they are not of the same age, then we can break the presumed association. Similarly, we can apply the same dating techniques to the skeletal remains and artifacts presumed to belong to the earliest modern humans: AMS radiocarbon dating of small (=0.3 g) organic samples (diagnostic pieces) and TL dating of heated (diagnostic) stone tools. The direct dating of human remains and particular classes of tools will allow archaeologists to compare like with like across regions, and to assess the validity and spatio-temporal coherence of our presumed technocomplexes, rather than quibble over the quality of association on a site-by-site basis. Only when we have placed our chronology on a firmer footing can the transition from Neanderthals to modern humans be reassessed.

World Overview

By archaeological convention, the Postglacial is defined as the period beginning with the final melting of the Scandinavian ice sheet at about 10 radiocarbon ka BP. This date also marks the conventional beginning of the Mesolithic period, seen as the continuation of a Paleolithic hunter-gatherer way of life adapted to the changed environmental conditions of the Postglacial – in particular, the change from the glacial steppe with its migrating herds of large mammals, to heavily forested environments with fewer resources. This is a view shaped by European data and intellectual history, in which the Mesolithic has traditionally been viewed as a period of cultural and demographic decline or stasis, marking time until Neolithic farmers from the Near East entered Europe, some 8 radiocarbon ka BP, replacing the hunter-gatherer way of life across the continent over the following three millennia.

Archaeological investigations now demonstrate that this notion of progressive evolution through uniform stages of development is greatly oversimplified. So far from being a period of cultural stagnation, these ‘Mesolithic’ millennia that preceded the development of full-scale village farming are now seen as representing a period of radical change and innovation, while Mesolithic achievements in their turn were built on developments, already well underway, in the closing millennia of the Last Glacial period (Mithen, 2003).

From an archaeological point of view, there are good reasons to extend the period of ‘Postglacial’ adaptations back to the beginning of the warming trend initiated at about 13 radiocarbon ka BP with the Late Glacial interstadials, and perhaps back to 16 radiocarbon ka BP, when sea levels began their sustained rise from the low point of the Last Glacial Maximum (see [Last Glacial Maximum GCMs](#)). As sea level rose to reach its present position about 6 radiocarbon ka BP, progressive inundation of the continental shelf removed extensive areas of lowland territory, breached inter-continental land connections, brought existing hinterlands within reach of milder ‘oceanic’ climates, and culminated in the creation of entirely new coastal landscapes. The impact of sea-level rise on paleoecology and paleogeography would have differed in different areas, but the effects would have been experienced worldwide. They were especially marked in regions with shallow continental shelves, such as northwest Europe, where large areas of hunting territory were lost, only to be replaced by the creation of shallow inshore waters, indented coastlines, and offshore islands and archipelagos, with more productive and more easily accessible supplies of fish, sea mammals, and intertidal mollusks.

It is during this Late Glacial period of changing environmental conditions, and especially between 13 and 12 radiocarbon ka BP, that we see the first stages of population expansion into new territory exposed by glacial retreat in northern Eurasia, the first

unequivocal evidence for the expansion of human populations into the Americas (Dillehay, 2000), the extensive use of micro-blade technologies with miniature bladelets and points blunted along one edge to provide inserts for hafted hunting weapons throughout large areas of the inhabited world, and the development of pottery in China, the Russian Far East, and Japan (Habu, 2004, Kuzmin et al., 2004).

Regions strongly affected by glaciation saw the rapid spread of populations into deglaciated territory, and the development of coastal and inland economies with significant dependence on aquatic resources along the shorelines of newly created lakes and coastlines throughout the northerly regions of Eurasia and North America. In subsequent millennia, subsistence economies throughout the world diversified into new niches exploiting a wider range of animal and plant food resources, including the first evidence for sustained and intensive use of marine resources on many of the world’s coastlines. In semi-arid environments at lower latitudes, stands of seed-bearing plants began to expand as climatic conditions improved, creating the basis for intensive harvesting of plant foods. In the Near East, this process was underway from as early as 12 radiocarbon ka BP, ultimately leading to agriculture based on cereal cultivation and domestic animals.

In temperate latitudes, the same climatic trends favored the expansion of woodland cover and reimmigration of deciduous trees, resulting in a complex and rapidly shifting geographical mosaic of vegetation and faunal patterns, in which the large herds of steppe animals such as reindeer, horse, and bison were replaced by woodland species of deer and wild boar. At the same time, these changes in vegetation brought with them new opportunities for food – nut-bearing shrubs and trees such as hazel, oak, and chestnut, and edible roots, leafy greens, and fruits. Hunting parties found new opportunities for seeking out prey such as chamois and ibex on the higher slopes of mountains above the treeline made accessible by deglaciation. Other resources such as birds and small mammals played a larger role, facilitating greater residential stability, larger communities of people, and smaller territories.

High-latitude regions with sub-Arctic conditions were first occupied from at least 10 radiocarbon ka BP on the coastlines of Norway and Alaska, and the final retreat of the North American ice sheets and the opening up of tundra environments in northern Canada and Greenland was closely followed by the expansion of ‘paleoeskimo’ populations into the high Arctic regions of North America between 5 and 4 radiocarbon ka BP. The occupation of this new niche was accompanied by exploitation of sea mammals alongside hunting of animals on land, and by dramatic and rapid expansions of human range. In Norway, 2,000 km of coastline was colonized in a matter of generations (Bjerck, 2008). In North America, 4,800 km of new territory from the Alaskan border to northeast Greenland was opened up in a few centuries (Fiedel, 1987).

Europe

The European landmass, broadly defined, provides an appropriate microcosm of these global trends (Figure 1). With a wide range of environments from the Eastern Mediterranean to the sub-Arctic shores of northern Scandinavia, and a long history of Mesolithic research stimulated by regular international meetings and periodic overviews (most recently Bailey and Spikins (2008), Larsson et al. (2003)), it provides an unparalleled range and richness of archaeological material. We can subdivide developments into three broadly defined periods: (1) Late Glacial, ca. 13–10 radiocarbon ka BP, characterized by expansion into newly available territory; (2) Early Mesolithic, ca. 10–8 radiocarbon ka BP, with consolidation of settlement and adaptation of hunting and gathering to new vegetational conditions, and a renewed phase of expansion into high-latitude maritime environments; (3) Late Mesolithic, ca. 8–5 radiocarbon ka BP, diversification of settlement and economy and greater regional differentiation, development of sedentary villages in productive aquatic environments on coastlines, rivers, and lakes, the husbandry of naturally occurring plant and animal resources, including evidence of environmental modification, and interaction with farmers and selective adoption of agricultural practices. These chronological

boundaries vary according to region, but nevertheless appear to coincide with major climatic changes, particularly in more northerly regions most sensitive to the effects of deglaciation.

Glacial Prelude

At the height of the Last Glacial, cold and aridity resulted in environments dominated by open steppe or forest-steppe vegetation that extended from the periglacial margins of the ice sheets in the north to the shores of the Mediterranean. Trees were confined to localized stands of coniferous trees in sheltered localities, whereas deciduous species were restricted to pockets of warmer and wetter conditions in refugia at intermediate altitude in the Pyrenees and the circum-Mediterranean mountain ranges. Human populations were largely dependent on migratory herd animals such as reindeer, horse, and bison in colder regions and wild cattle, red deer, gazelle, and the steppe ass in the south and southeast. Woolly mammoth were abundant on the more extensive steppes of eastern Europe and were an important source of meat, bone for artifacts and fuel, and ivory for decorative items. Plant foods were scarce nearly everywhere, though probably exploited where available.

Human populations were distributed in small and mobile bands with large annual territories and social contacts with

Figure 1 Map of Europe showing principal topographic features and sites (see text). Shaded areas indicate land above about 1000 m, and the dashed line indicates the maximum extent of the Scandinavian ice sheet at the glacial maximum.

neighboring bands over long distances, signaled in the archaeological record by the movement of exotic materials such as marine shells and rare and fine-grained flint many hundreds of kilometers from their sources. The most favorable environments, the largest concentrations of archaeological sites, and the highest population densities were in southwest France and northern Spain in the west and the riverine basins of eastern Europe and the Ukraine in the east. These were also the centers of cultural innovation and of social aggregation and ritual, associated in the west with the flowering of Franco-Cantabrian rock art, and in the east with the production of a rich variety of portable art and the construction of dwelling structures built from mammoth bones (see [Interactions with Hominids](#)).

Late Glacial Expansion

It was from these centers that human populations first expanded into newly accessible territory as the ice sheets retreated and climate ameliorated. Many of the animal species of former significance moved their ranges northward, as with reindeer and horse, or became extinct, as with mammoth and bison, and were replaced by forest or forest-edge species such as elk, red deer, roe deer, cattle, and wild boar, according to regional and local circumstances.

From about 13 radiocarbon ka BP onward, settlements associated with hunting of reindeer and, later, horse, cattle, and elk, became established across the north European plain in a broad swathe from the British lowlands in the west to the Crimea in the east ([Dolukhanov, 2008](#), [Tolan-Smith, 2008](#), [Zvelebil, 2008](#)). Stone industries were characterized by tanged points for hafting on the ends of spear or arrow shafts, and by 'knife' blades with a curved and blunted edge. The southern end of the North Sea was still dry land at this period and the recovery of an antler harpoon dredged up from the Leman and Ower Bank and dated to 11.7 radiocarbon ka BP shows that this territory was used from an early period ([Tolan-Smith and Bonsall, 1999](#)). Variations in the proportion of these artifacts and minor differences in morphology of the key artifact types have given rise to a variety of cultural labels, Swiderian in Poland, Hamburgian, Bromme, and Ahrensburgian in northern Germany and Denmark, and Federmesser and Creswellian in the Low Countries and Britain. Whether these represent stylistic markers of distinct social groupings or functional adaptations to different types of weapons and prey species is unclear. The smaller and lighter tanged points of the Ahrensburgian, associated with the final cold phase of the Younger Dryas period between 11 and 10 radiocarbon ka BP (see [Younger Dryas Oscillation, Global Evidence](#)) could well have been used as arrow points, since actual bows have been recovered from this period. At any rate, the similarities across this vast territory are as impressive as any differences, with relatively small settlements, specialized toolkits of stone and antler, and a considerable degree of mobility. Importation of raw materials for making artifacts from favored sources over distances of 150 km or more reflects both the extended lines of communication in small mobile populations engaged in the early stages of colonizing new territory and lack of familiarity with less suitable materials available nearer to hand or the absence of any need to use them.

The Early Mesolithic

Technologically, there is no obvious break with the preceding period, although there is a greater diversity of raw materials, techniques of stone working, and tool types. Microlithic stone tools made from bladelet segments proliferated into new geometric forms, particularly rectangular pieces, triangles, and crescents. Many of these were most probably used to provide replacements for arrow tips, and the bow and arrow were widely in use throughout Europe during this period. Some may also have been used as replaceable components in other multipart tools such as knives with bone or wooden handles. There was also a general diversification of artifact types made from stone, bone, antler, and wood throughout the Mesolithic period, including macrolithic tools of worked antler, flaked flint, or other stone, and polished slate, used for working wood, digging the ground, or processing sea-mammal carcasses and fish. Harpoons of bone or antler and bone fishhooks are evidence of new technologies for exploiting marine and aquatic resources. Wooden artifacts include dugouts, paddles, fish weirs, spear and arrow shafts, and timber-framed houses. Artificial dwelling structures are more widely in evidence and range from lightly built tent-like structures to substantial stone-built constructions, depending on the available raw materials, climatic conditions, the function of the structure, the nature of the settlement, and the size and permanence of the resident population.

In areas of the north European plain, first occupied in the preceding Late Glacial, there was a consolidation of settlement across this extensive lowland region, a trend already apparent toward the end of the Late Glacial, but one that became more marked with the onset of the Preboreal period after 10 radiocarbon ka BP (see [The Last Interglacial](#)). The archaeological record indicates more sites, greater use of local raw materials, a wider range of game animals, and a marked preference in site locations for lake-edge settings, with evidence for fishing and fowling as well as hunting. Star Carr in Britain, dated at about 9.5 radiocarbon ka BP is an early example of this pattern, with broad-blade industries typical of the early Mesolithic period, flaked stone axes, barbed harpoons of red deer antler, antler mattocks, and faunal remains of wild cattle, red deer, roe deer, elk, and boar, though fish are absent here ([Mellars and Dark, 1998](#)). The presence of a wooden paddle indicates the use of water transport, most probably dugouts. Similar sites are well documented in Denmark in association with the Maglemosean culture ([Blankholm, 2008](#)), and similar groupings are found in Poland, southern Sweden, the eastern Baltic and Russia ([Dolukhanov, 2008](#), [Zvelebil, 2008](#)). At the very end of this period, about 7.8 radiocarbon ka BP, the Arctic island of Zhokov in the East Siberian Sea was first visited when still accessible from the Siberian mainland, with a fauna dominated by reindeer and polar bear ([Pitul'ko, 1995](#)). Nuts, greens, roots, seeds, and fruits became more widely available and other resources such as birds and small mammals created more varied and diverse paleodiets, but in all cases seasonality evidence suggests seasonal occupations and relatively small social units of one or a few families, implying a large degree of residential mobility.

Maritime adaptations

The earliest use of marine resources is obscured by the lowered sea levels that persisted throughout the glacial period and the

removal or submergence of relevant evidence before sea level approximated its present position about 6 radiocarbon ka BP. This problem of differential visibility of evidence is especially acute on the shallower and broader stretches of continental shelf around the coastlines of the North Sea basin and northern France, but even on the steeply shelving coastlines of southern Europe, the shorelines of the glacial maximum would have been at least 5 km away, far enough to take most marine resources out of reach of sites located on the present-day coastline. Underwater survey and excavation are beginning to reveal new evidence, and it seems plausible to argue that late Paleolithic hunters were hunting seals and taking other marine resources along these now submerged coastlines from an early period (Fischer 1995, 1996; Flemming 2004).

Quantities of marine mollusk shells appear in the coastal cave deposits of northern Spain, such as La Riera and El Juyo, from as far back as the glacial maximum, with evidence for increased quantities in the Late Glacial period (Straus, 2008). Cueva de la Nerja in southeast Spain contains evidence of marine mollusks, fish, seal, and birds, associated with an early stage of the Late Glacial dating between about 14 and 12 radiocarbon ka BP (Morales et al. 1998). Given that shorelines were still at some distance from the present coastline, this is a significant indication of interest in marine resources and most probably only the visible tip of a more extensive pattern of marine exploitation (Bailey and Craighead, 2003). As shorelines approached their present position, thick shell middens with many millions of discarded mollusk shells begin to appear. The earliest group of such sites in the Iberian Peninsula is the Asturian shell middens, accumulated in rockshelter mouths on the north Spanish coast between about 9 and 6 radiocarbon ka BP. Here, as with the larger and more numerous shell middens that abound during the Late Mesolithic, hunting and gathering of resources on land continued alongside the collection of mollusks and other marine resources.

In the eastern Mediterranean, the occupants of the Franchthi Cave on the Argolid Peninsula of southern Greece were importing obsidian from the island of Melos 11 radiocarbon ka BP, which would have required a sea journey of 100 km by the direct route, or a series of sea crossings of at least 20 km by a more circuitous route. However, apart from a few limpet shells, evidence for the exploitation of marine resources does not appear in the Franchthi deposits until somewhat later in the sequence, most probably because the coastline was still too far away (Pluciennik, 2008).

A notable exception to this general picture of submergence and loss of coastal archaeology is the Norwegian coast, which has undergone substantial isostatic uplift following the removal of the Scandinavian ice sheet, so that 13-ka-old shorelines formed when the eustatic level of the sea was still about 50 m below the present are now elevated above present sea level along much of the Norwegian coastline.

Despite the opportunities for preservation of early coastal sites and the fact that the Norwegian coastline was ice free from an early period, there is no convincing evidence of human occupation, apart from stray and ambiguous finds, until about 10 radiocarbon ka BP, when numerous sites appear all along the Norwegian coastline in association with locally named Komsa and Fosna cultures characterized by large numbers of flake adzes and tanged points of Ahrensburgian type.

Preservation of organic materials is almost nonexistent, so that there are few indications of the animals exploited, but the location of the sites (some of them on offshore islands), the nature of the resources available, and the need for substantial intake of animal fats for human survival in these northerly regions indicate that marine resources and especially sea mammals must have been a major source of subsistence, while the flake adzes would have been well suited for scraping blubber from seal carcasses (Bjerck, 2008). The sites on the three large islands of Vega, some 20 km offshore, provide a good example. These were occupied from the earliest period, and by about 8.5 radiocarbon ka BP comprised an interrelated network of some 12 settlements scattered across the islands. The largest site of Åsgarden was associated with the best natural harbor and had evidence of solid circular dwelling structures with foundations partially excavated into the subsoil ('pit dwellings'), stone or turf walls, and a wide range of artifacts suggesting a residential base. The other sites were smaller with a narrower range of tool types indicating shorter-lived occupations for specialist activities.

The absence of earlier sites on the Norwegian coast may be due to the lack of technology or skills to make the seaworthy boats that would have been essential for sea travel in the region. Or it may be that the resource options available for human survival were too narrow and too risky to encourage settlement until the retreat of the Scandinavian ice sheet and the expansion of the Gulf Stream created more productive conditions on land and at sea.

At about the same time, during the Preboreal period, the British Isles also witnessed a new phase of expansion northward and westward beyond the lowland regions of England, with a number of new settlements appearing around the coastlines of Scotland and in the Western Isles, dating from about 9.5 radiocarbon ka BP (Tolan-Smith, 2008). Ireland, which had never had a passable land connection to mainland Britain, was also occupied for the first time. As in Norway, the appearance of the Gulf Stream would have been a significant attraction to the new settlement. Seaworthy boats would have been essential for navigating the Western Isles and especially for the crossing to Ireland, regarded as one of the most treacherous sea crossings in the British Isles. Sturdy dwelling structures would also have been essential in the harsher winter climates of the north. Faunal preservation on many of these sites is poor, but Mt. Sandel in Northern Ireland has preserved evidence of salmon fishing and boar hunting, postholes indicating substantial dwelling structures and pits that could have been used for food storage. The coastal site of Howick on the North Sea coast of Northumberland in northern England belongs to this phase of expansion, and has yielded traces of a substantial timber-framed dwelling and evidence of sealing and boar hunting.

The Late Mesolithic

During this period, sea levels stabilized in most parts of Europe at about their present position, resulting in the development of estuarine and inshore mudflats, and climate became slightly warmer and wetter – the Climatic Optimum (see Overview) – with temperatures 2–3 °C higher on the average than today's. These changes would have had a number of generally

beneficial effects on the productivity of coastlines, lakes, and rivers, and during this period we see the proliferation of large numbers of sites and settlements in these settings, many of them associated with permanent villages, food storage, cemeteries, and indications of social ranking. More specialized sites for hunting or gathering of plant foods associated with mobile settlement patterns continued in the less productive regions of Europe, or as outlying locations visited by hunting parties from residential bases elsewhere. Pollen evidence of woodland clearance in southern Sweden, southern Finland, and eastern Latvia (Zvelebil, 2008), and in upland regions of Britain (Tolan-Smith, 2008) is associated with deliberate clearance to improve the productivity of food-bearing shrubs and plants, either for direct human consumption or to concentrate animal resources. Freshwater or saltwater fish were a major source of protein, the domestic dog was widely in evidence, and pigs were commonly hunted, and may have been husbanded without necessarily involving biological domestication, the combination of fish, pigs, and nuts creating a powerful 'package' of resources capable of sustaining large communities.

The technological characteristics of this period represent a continuation or elaboration of existing trends. Among the geometric microliths, trapezes and rhomboid-shaped pieces replaced the earlier shapes across extensive territories. Pottery also came into regular use in some areas. The earliest examples occur between 9 and 7.3 radiocarbon ka BP in European Russia and ceramic containers were widely used from 6.5 radiocarbon ka BP in the Baltic and southern Scandinavia in late Mesolithic contexts.

Shell mounds

Coastlines are associated with shell mounds of varying size and number, the largest and best known grouping being the Ertebølle in Denmark, dated between about 6.5 and 5 radiocarbon ka BP, the largest mound, as at the type site of Ertebølle itself, being several hundred meters long and several meters thick. These sites were built up slowly over many centuries of repeated use and discard of oyster shells and other refuse, and over 400 shell mounds have been recorded. The larger sites were residential bases with a full range of artifacts including microlithic arrow barbs and flaked axes, an antler and bone industry, and pottery jars and bowls. Food remains include sea and land mammals, fish, and fowl (Blankholm, 2008). Marine resources were most probably the major source of protein, among which fish rather than shellfish were the major food item, a conclusion reinforced by stable-isotope analyses of human bones recovered from these sites. Coastal sites without mollusk shells are just as common and probably played the same role in the settlement system, occurring on shorelines lacking local supplies of oysters. Some of the coastal settlements of this period have been submerged in shallow water because of isostatic submergence, resulting in spectacular conditions of organic preservation, notably at the underwater settlement of Tybrind Vig, which produced a dugout, a paddle richly incised with geometric designs, and large numbers of wooden stakes associated with a landing stage and a fish weir. Many other submerged sites have been discovered in Danish waters, including other examples of fish weirs, suggesting a major investment in communal facilities.

Other well-studied concentrations of shell mounds are those on the small island of Oronsay in the Western Islands of Scotland, used between about 6 and 5.5 radiocarbon ka BP for seal hunting, fishing, and the collection of limpets – perhaps for fish bait (Tolan-Smith, 2008), and the Portuguese shell mounds on the Muge and Sado tributaries of the Tagus estuary (Straus, 2008). Around the Mediterranean coastline, fishing and shellgathering were combined with gathering of plant foods and hunting of mammals, supporting year-round occupations in some cases, notably at Franchthi Cave in Greece and the Uzzo Cave in Sicily, while the offshore islands of Mallorca, Corsica, Sardinia, and Cyprus were occupied or visited (Pluciennik, 2008). The apparent 'explosion' in the numbers of these coastal sites may be misleading, given that earlier coastlines are now mostly submerged in much deeper water.

Lake and river settlements

Elsewhere in Europe, large settlements have been recorded on the edges of lakes and rivers. Notable examples are Tågerup in Sweden (8–6.5 radiocarbon ka BP), with timber dwellings, wooden jetties for boats, and basketry used in trapping and carrying fish. On the Latvian coast, Sārņate (7–4 radiocarbon ka BP) has wooden houses with evidence of seal hunting, fishing, and large-scale processing of water chestnuts. In N. Finland, Kierikki (4.8–3.8 radiocarbon ka BP) on the estuary of the River Li revealed more than 300 house floors of pit dwellings, very large pottery jars used for storing seal oil, a large stone structure 50 m × 30 m suggesting a communal or ritual purpose, and evidence of long-distance trade in flint, greenstone, amber, and copper (Zvelebil, 2008). In the Iron Gates region on the middle reaches of the Danube River is a group of sites dated between about 8 and 7 radiocarbon ka BP, such as Lepenski Vir, Vlasac, and Schela Cladovei, with trapezoidal dwelling structures and faunal remains including deer, dogs, fish, freshwater mollusks, and land snails (Bonsall, 2008). Fish include the migratory sturgeon, which can grow to an individual weight of 150 kg, and stable isotope analyses of human bones indicate a major dependence on fish protein.

Burials and rock art

Burials are common, either in intimate association with domestic dwellings or as separately demarcated cemetery areas. The earliest example is at Aveline's Hole, a cave in the Cheddar Gorge of southwest England, with a date of ca. 9.1 radiocarbon ka BP, with more than 70 human burials, interpreted as the cemetery of a larger social group (Tolan-Smith, 2008). Olenii Ostrov on an island in Lake Onega in Karelia, dated at about 7.5 radiocarbon ka BP, had over 300 burials. At Zvejnieki in Latvia, 315 burials have been excavated indicating repeated use between 8.2 and 4.2 radiocarbon yr BP. Grave goods and the position of the skeletons indicate a variety of burial rites and evidence of social ranking based on age, gender, personal wealth, clan membership, and the presence of shamans (Zvelebil, 2008). The Portuguese shell mounds of the Muge River are also estimated to have contained at least 300 burials (Straus, 2008). In Denmark, human remains are rare in the Ertebølle shell mounds but 18 burials were found at the coastal settlement of Vedbaek. At Skateholm in southern Sweden, also belonging to the Ertebølle culture, a total of 85 burials

were recovered including evidence of a wooden mortuary structure (Blankholm, 2006). There are many instances of violent deaths, suggesting conflict associated with increased competition or territoriality.

Rock art is commonly regarded as absent in the Mesolithic period, an absence taken as evidence of cultural impoverishment compared with the Upper Paleolithic. However, rock art is in fact quite common, as are decorative artifacts, but concentrated in the new centers of population growth located in different regions from their Upper Paleolithic predecessors, providing additional insights into ritual and symbolism. Well-dated rock art is present in northern Norway by about 9 ka BP with naturalistic representations of elk, reindeer, bear, whale, and seal. Many hundreds of sites have been recorded in Norway and Sweden with images of anthropomorphs, deer, boats, sea mammals, bear, water birds, fish, reptiles, tracks, hunting and fishing implements, and abstract designs. One of the largest such concentrations is the site of Nämforsen (5.5–3.5 radiocarbon ka BP) in Swedish Norland, which was a major focus of ritual and seasonal aggregation for settlements in the surrounding region. At the other end of Europe is the Levantine rock art of eastern Spain, with schematic and naturalistic representations including hunting scenes and humans, and the Addaura Cave in Sicily (Pluciennik, 2008).

Conclusion

The major driving force behind these postglacial adaptations was the changing environmental conditions associated with deglaciation and climatic amelioration, which created new territories for human settlement, new supplies of food and raw materials for subsistence, new technological demands for tools, shelter, and transport, and new opportunities for population growth. These changes resulted in major reconfigurations of social geography, with expansion of human populations into new territory and the growth of new centers of population density, often associated with permanent ‘villages’ repeatedly occupied on a year-round basis by large communities, or with aggregation sites that formed a seasonal focus for more widely dispersed populations. The more ecologically productive environments capable of supporting higher population densities were often associated with a rich ritual and symbolic life and evidence of social differentiation. The contrasts often drawn with the Upper Paleolithic period thus reflect changes in the geographical distribution of population centers and the occupation of ecologically productive regions that were unavailable during the Last Glacial period, rather than an overall advance in social or economic complexity. It was these closing millennia of the hunting, fishing, and gathering way of life, in their turn, that witnessed the emergence and synthesis of the technological, economic, and social capabilities on which the later developments of agriculture, urban civilization, and long-distance trade were founded.

Introduction

The study of fossil beetles (Coleoptera) from Quaternary deposits began in earnest in the 1950s in Britain, and has since spread to many parts of the world, most recently to Australia, New Zealand, and Japan. Fossil beetle research has led to many exciting breakthroughs in the understanding of the pace and intensity of climate change in terrestrial landscapes. In many ways, beetles are the ideal proxy for tracking terrestrial environmental change.

The Perfect Proxy?

If one were to design the ideal source of biological proxy for the reconstruction of Quaternary terrestrial environments, certain aspects of the nature of this ideal organism would have to conform to the following guidelines:

1. It must be sensitive to environmental change. Organisms that are able to withstand decades or centuries of adverse climate *in situ* before eventually dying out would be of far

less use than organisms that simply could not survive such adversity.

2. There should be great species diversity within the group of organisms to be studied. Greater diversity yields more precise and diverse information on paleoenvironments. Taxonomic groups with only a few dozen species necessarily offer less precise information about past environments than groups with many thousands of species. Each species has its own ecological niche, so by studying the fossil record of a group that represents thousands of ecological niches, one is able to piece together a broad spectrum of information about past environments (climate, soils, water quality, and vegetation).
3. It should be highly mobile, and thereby able to respond rapidly to environmental change by rapidly shifting its distribution into new areas where the environment is suitable. This quality ensures little or no problem with 'migration lag,' wherein an organism requires decades, centuries, or even millennia to become established in regions with potentially suitable environments.
4. It should have an abundant, well-preserved fossil record. This allows regional reconstructions to be built up for given

time intervals, based on multiple study sites containing assemblages of the fossil type in question. If the fossil remains of an organism are too scarce, or too poorly preserved to be identified, then their fossil record will contribute little to regional paleoenvironmental reconstructions.

5. It should be readily identifiable to the species level. Even if a group of organisms satisfy the first four criteria, their fossil record will be of limited value if their remains cannot be specifically identified. There is often a great deal of ecological variation among the species in a given genus, so a generic identification provides little that is useful to paleoenvironmental reconstruction.
6. It should have many species with narrow ecological or climatic tolerances. Again, this harkens back to the issue of specificity. The more specific the environmental requirements of the organism, the more specific the reconstruction that can be made, based on its presence in the fossil record. This criterion works together with criterion 2. If taxonomic groups with a great deal of species diversity also contain many species with very narrow ecological or climatic tolerances, then a complex mosaic image of the paleoenvironment can be constructed.
7. None of the above criteria are of much use unless the taxonomic group has remained extant throughout the study period one is interested in. If the group of organisms has gone extinct, no matter how diverse, abundant, or well-preserved, then only educated guesses can be made about the ecological or climatic requirements of the ancestral forms. The modern ecological and climatic data available for the surviving species in such a group of organisms can never be fully applied to extinct species.
8. Finally, it is a great help to the paleoecologist if the proxy group of organisms is well known to science. In other words, if a group of organisms has been well studied in recent times, then paleoecologists have at their disposal a great body of data, built up through many generations of scientific study, concerning the modern ranges and ecological requirements of the species.

The reason that beetles (Coleoptera) are so useful as proxy indicators of past terrestrial environments is that they fulfill all of these requirements. Beetles are the most diverse group of organisms on Earth, with more than 1 million species known to science. A large proportion of beetle species are known to be quite sensitive to environmental change, and to shift their distributions across continents in order to become established in regions of suitable environment (Elias, 1994). As discussed in this section of the encyclopedia, beetles have a well-preserved, abundant fossil record in many regions of the world. Beetle exoskeletons are reinforced with chitin, a highly durable compound that resists decay in waterlogged and other anoxic sedimentary environments. That chitinous exoskeleton is covered with taxonomically useful characters on the main body parts, including the head capsule, thoracic shield (pronotum), and wing covers (elytra). In many study regions, paleoentomologists are able to specifically identify upwards of 50% of these fossil beetle sclerites; in some well-studied regions, this percentage climbs closer to 75%. Quaternary beetle faunal assemblages frequently contain hundreds of identified species, more than any other group of organisms preserved in Quaternary deposits.

Many beetle species are stenothermic, adapted to a narrow range of temperatures (Figure 1). Predatory and scavenging families of beetles comprise less than half the total number of families, but their species' numbers are often proportionally high in fossil assemblages. These are the two groups that receive the most attention in paleoclimatic reconstructions. The rationale behind this decision is that predators and scavengers are not tied to particular species of host plants, and so are able to become established most rapidly in new regions in response to changing climates. For instance, the Pleistocene fossil record indicates that these groups have colonized newly deglaciated landscapes within a few years of ice-margin retreat (Coope, 1977). Perhaps because of beetle mobility in the face of changing environments, the fossil evidence strongly indicates that nearly all species found in Quaternary assemblages remain extant today. It appears likely that beetle populations never remained genetically isolated for sufficient lengths of time in the last 2.6 My to develop new species. The constant mixing of gene pools through shifting distributions, in response to 50+ glacial-interglacial cycles, prevented this from happening (Coope, 1978). Finally, beetles are some of the best-studied groups of insects, with modern ecological requirements and ranges well understood for many species living in the temperate and high latitude regions (where the vast majority of fossil investigations have taken place).

Where Fossil Beetles Are Found

Fossil beetle assemblages have been recovered from a wide variety of sedimentary environments, especially anoxic waterlain sediments that concentrate the remains in layers of organic detritus. Lacustrine (lake and pond) sediments have yielded abundant, diverse assemblages of fossil beetles, especially in deposits from the littoral zone and where a stream enters the lake or pond (Figure 2). Such deltaic deposits can yield astonishing numbers of fossil beetle specimens. Fluvial sediments also yield fossil beetles. The most productive type of fluvial deposit is an accumulation of organic detritus, laid down in secondary channel bends, backflows, and pools between riffles (Figure 3). Bogs, fens, and mires can also yield good accumulations of fossil beetles, especially in locations representing the edge of such bodies, where there is increased input from the upland beetle fauna (Figure 4). One of the more unusual types of deposit yielding beetle remains are the middens of certain rodents, including packrats or woodrats (*Neotoma*) – the native group of North American rats. Their middens (Figure 5), intermittently wet and sticky from rat urine and feces, serve as traps for beetles entering the shallow caves and rock shelters of desert and semiarid regions where these rats thrive (Elias, 1990). Unlike the waterlogged sediments of lakes, rivers, and bogs, packrat middens preserve beetle (and other arthropod) exoskeletons in extremely dry conditions, sometimes mummifying their soft tissues.

Methods of Sampling and Extraction

When sampling the kinds of sediments discussed above, the aim is to obtain a sufficient quantity of material to yield at least a liter of organic detritus. The details of sampling and

Figure 1 Modern European distributions of stenothermic beetle species found in British Pleistocene deposits. (a) Cold-adapted species and (b) warm-adapted species.

extraction procedures are discussed in [Elias \(1994, 2010\)](#). In lacustrine sediments that are only 3–5% organic detritus by volume, this requires the extraction of many kilograms of sediment, followed by wet-screening to isolate the organic fraction. Generally, the quantity of sediment obtainable by

piston coring of lake and pond sediments is insufficient to yield adequate amounts of detritus. While some success has been achieved by taking multiple, large diameter cores, this is not often practical. The best results are obtained by sampling exposures of sediments, either natural or man-made. Natural

exposures include cutbanks of streams and ocean and lake bluffs. Man-made exposures include gravel and clay pits, irrigation ditches, trenches, and building sites.

The sequence of steps in extraction and mounting of insect fossils is summarized in [Figure 6](#). Fossil insect extraction is

relatively safe, cheap, and easy. The only lengthy process that may be involved is the pretreatment of samples to disaggregate the organic detritus from inorganic matrix (such as calcareous sediments and clays), or to soften and then disperse felted peats or lignite. Processing procedures are largely a matter of personal preference and availability of equipment, and some workers use a slightly different procedure than the one discussed below. For instance, Russian workers sometimes prefer to skip the kerosene flotation step discussed below, and sort through entire samples of washed organic detritus, in order to

Figure 6 Flow chart of fossil beetle sample processing for kerosene flotation. Reproduced from Elias SA (1994) *Quaternary Insects and Their Environments*. Washington, DC: Smithsonian Institution Press.

maximize the recovery of such heavy-bodied groups as weevils (Curculionidae) that sometimes do not rise to the top during flotation. Japanese workers studying peat deposits prefer to split the individual layers of peat and examine each layer under a microscope.

Once disaggregated organic detritus is obtained, the next step is to wet screen the sample in a 300 μ m sieve. This process removes fine particles, such as silt, that may fill the concavities of rounded insect sclerites. Once the detritus has been screened, the residual material is placed, still damp, in a large bowl with a spout, or a rectangular dishpan, and processed by kerosene flotation to isolate and concentrate insect fossils. Kerosene or other lightweight oil is added to cover the sample, and gently worked into the sample by hand for several minutes. The oil adheres to the insect sclerites but not to plant detritus. The remaining kerosene is decanted from the bowl and cold water is vigorously added to the oily detritus. In most samples, nearly all of the insect sclerites will rise to the top, and float at the oil–water interface. Within 15–60 min, most plant residue sinks to the bottom of the bowl, and the now-concentrated insects may be decanted onto a screen, to be washed gently in detergent and dehydrated in 95% ethanol before microscopic sorting. Small samples should be sorted completely, rather than processed with kerosene. Also, samples that may need to be submitted for radiocarbon dating should not be exposed to kerosene.

Specimen sorting is done under low power (10 $\times$) binocular microscope in alcohol or water. Specimens may be stored in

vials of ethanol, or more robust specimens may be mounted with gum tragacanth (a water-soluble glue) onto micropaleontological slides. Identification of fossil specimens is usually done through comparison with modern identified specimens (often from museum collections). This is another potentially lengthy process.

Exoskeletal Parts Preserved in Quaternary Deposits

The chitinous remains of beetles often preserve extremely well in Quaternary sediments, and can be matched exactly with modern specimens. The principal sclerites that are used in the identification of Quaternary beetles are the head, pronotum, and elytra (Figure 7). The male genitalia (aedeagi) are likewise reinforced with chitin, and are sometimes recovered from compressed groups of abdominal segments found in fossil assemblages. The aedeagus is often the most diagnostic sclerite in the identification of species, especially in genera that contain dozens or hundreds of species.

Useful Characters

The process of identification begins with the shape and size of the main exoskeletal parts. Often times colors derived from pigments are preserved, and color patterns can be quite useful in the identification of groups that have spots, stripes, and other noticeable color variations on the elytra or pronota.

Figure 7 The ground beetle, *Pterostichus leconteianus*, with principal body parts found in fossil assemblages identified. Photograph by the author.

Metallic coloration preserves extremely well because it is based on surface microsculpture, rather than pigments. The depth, shape, and distribution of such surface features as striae, punctures, and microsculpture are all potentially diagnostic characters, as are the presence and placement of scales and setae in some groups. As discussed above, the size and shape of the aedeagus is one of the most diagnostic characters for beetles, although these are not as commonly found as heads, pronota, and elytra.

Basic Assumptions for Use in Paleoecology

There are several basic assumptions made in the reconstruction of paleoenvironments, based on fossil beetle assemblages. These assumptions fall within the framework of uniformitarianism in the sense that it is assumed that ancient beetle populations had the same environmental tolerances and behavior patterns as their modern counterparts.

Species Constancy Throughout the Quaternary

There are three lines of evidence that support the assumption that the beetle species found in Quaternary deposits are the same species that live today. The first is that the morphology of their exoskeletons has remained constant. In other words, no differences can be found between the fossil specimens and their modern counterparts that fall outside of the boundaries of known variation within the modern species. The youngest beetle fossils that exhibit morphological variations outside the bounds of modern species come from fossil assemblages that date to the Pliocene/Pleistocene boundary, approximately 2.6 Ma. However, there are many reliably identified beetle

species from Pliocene assemblages that exactly match modern species. A full discussion of this topic can be found elsewhere in this encyclopedia. The second line of evidence for Quaternary species constancy comes from the stability of shape and size of fossil aedeagae, as discussed in section 'Exoskeletal Parts Preserved in Quaternary Deposits,' above.

The third line of evidence deals with the issue of constancy of physiology, as expressed in environmental tolerances. This issue can only be dealt with indirectly, as the exoskeletal evidence does not speak to it. However, what has been repeatedly observed in fossil beetle assemblages from sites throughout the world and ranging in age from early to late Quaternary times, is that the species found together in fossil assemblages remain ecologically compatible today, even if they no longer live in the same geographic regions. For instance, a fossil assemblage associated with Pleistocene periglacial environments may contain a mixture of species found today in arctic and alpine habitats, in various parts of the Northern Hemisphere. Conversely, an interglacial fauna may be found to contain large numbers of warm-adapted beetle species that today are found in a variety of temperate or subtropical habitats in various regions. In order for this persistence of ecological compatibility to occur, one of two scenarios must be invoked. Either whole suites of species have evolved unidirectionally during the Quaternary, so that their past environmental tolerances have changed together, or their environmental tolerances have not changed at all. The latter scenario seems by far the likeliest, as evolutionary theory indicates that each species evolves separately from others, in response to its own unique set of selective pressures (Elias, 1994).

Usefulness of Beetles as Paleoclimate Proxies

Insect ecologists support the idea that insect abundance and diversity may be controlled by biotic factors (e.g., predators, competition) in the central part of a species' range, but that climatic factors probably limit populations toward the edges of these ranges. Oxygen isotope records from deep sea sediments and polar ice cores have shown that large-scale, climatic change was practically a constant feature of Pleistocene environments, it would appear that the shifting of insect distributions in response to these changes would have placed a large proportion of populations in this 'abiotic factor' zone of their respective ranges, during much of the Pleistocene.

Thermal Tolerances of Beetles

The modern distribution patterns of many beetle species in the temperate and high latitudes have been shown to coincide closely with climatic zones. The distribution of individual species reflects temperature regime, especially summer warmth and degree of seasonality (i.e., annual temperature range). Stenothermic species with limited thermal tolerances are found in most fossil assemblages (Figure 1). The physiology of stenothermic species is closely tied to their thermal requirements. Experiments on metabolic rates of ground beetles (Carabidae; Thiele, 1977) showed that beetles' optimal metabolisms correspond with their thermal tolerance zones. This phenomenon is strengthened during the process of cold-

Figure 8 (a) Modern North American distribution of the ground beetle, *Bembidion grapii*, and (b) species climate envelope for *B. grapii*, based on climatic parameters (T_{max} and T_{range}) of collecting localities shown in (a).

hardening, which takes place in late summer or fall. In preparation for winter cold, ground beetles in northern regions become progressively cold-adapted (able to function at cold temperatures). Under these conditions, the beetles' metabolic rates peak at low temperatures, and they may become paralyzed or die if exposed to the temperatures they experience in mid-summer.

Mutual Climatic Range Analysis of Fossil Assemblages

The mutual climatic range (MCR) method of paleoclimate reconstruction is based on the concept that the proxy

organisms (in this case, beetles) live within the bounds of a set of climatic parameters, as defined by the climatic conditions within their geographic range. Thus beetles live in a quantifiable piece of climate space. In the MCR method, the first step is to develop a climate envelope for the species of predators and scavengers that are found in the fossil assemblage (Figure 8). The full method is described in Atkinson et al. (1986) for European studies, and by Elias et al. (1996) for North American studies. These envelopes typically are defined on the basis of the mean July and mean January temperatures of the locations where the species are known to occur today. The climatic parameters of each of these localities were plotted

Figure 9 An example of the application of the mutual climatic range (MCR) method, showing the overlap of the climate envelopes of four species of cold-adapted beetles. In nearly all cases, far more species are involved in MCR reconstructions. The number is limited here, for the sake of visual clarity.

on diagrams of mean July temperature ($T_{\max}$) versus the difference between the mean July and mean January temperature (T_{range}). Once the individual species' climate envelopes are created, then the envelopes for the species found together in a fossil assemblage are put together to find the area of overlap in climate space. This area is the MCR of the faunal assemblage. In the example shown in [Figure 9](#), the climate envelopes of just four cold-adapted species are combined to produce the MCR, shown in bright yellow.

European and North American MCR studies have focused on species that are predators or scavengers. Plant-feeding species have been avoided, because of the possibility that the migration rate of the host plants of these beetles may lag behind climatic change. For instance, in recently deglaciated landscapes, the process of ecological succession from bare mineral soil to mature forest stands may take many centuries to achieve. Predators and scavengers are able to exploit such landscapes as part of the earliest pioneering biological communities, as soon as the climate is suitable ([Elias, 1994](#)).

Modern tests of the reliability of the MCR method have been performed for the European and North American beetle faunas. These tests compared predicted with observed temperatures for a broad spectrum of sites, using the MCR of species found today at localities to predict modern temperatures of those localities, and comparing these predictions with modern climatological data for the same sites. For 35 sites in North America, a linear regression of actual versus predicted $T_{\max}$ values yielded an r^2 value of 0.94. A regression of observed versus predicted $T_{\min}$ values yielded an r^2 value of 0.82. The standard deviation for $T_{\max}$ was 0.7 °C and for $T_{\min}$ was 10 °C. Similarly for Europe, a linear regression of actual versus predicted $T_{\max}$ values yielded an r^2 value of 0.88, and a regression of observed versus predicted $T_{\min}$ values yielded an r^2 value of 0.88. The standard deviation for $T_{\max}$ was 0.83 °C, and for $T_{\min}$ was 2.42 °C. Beetles living in regions with cold winters are poor indicators of winter air temperatures because they seek shelter from exposure to winter air through various means (e.g., burrowing in mud, leaf litter, under bark or stones).

The MCR method has allowed paleoentomologists to produce quantified paleotemperature estimates for both summer and winter seasons for hundreds of fossil assemblages, ranging in age from late Tertiary ([Elias and Matthews, 2002](#)) to the late

Holocene ([Lavoie and Arseneault, 2001](#)). Regional summaries of MCR reconstructions have been prepared for northwest Europe ([Coope, 1987](#); [Coope et al., 1998](#)), eastern and central North America ([Elias et al., 1996](#)), the Rocky Mountain region ([Elias, 1996](#)), and Alaska and the Yukon Territory of Canada ([Elias, 2001](#)). The main results of these studies are discussed elsewhere in this encyclopedia. The principal findings in both Europe and North America are that late Pleistocene climatic changes were rapid and often of large-scale. Interglacial climates were at least 3 °C warmer than today in some regions, but during the Last Glacial Maximum (LGM), $T_{\max}$ was depressed by 8–10 °C in most temperate regions. The LGM summer temperatures of the Arctic regions were only depressed by 3–5 °C in Beringia. $T_{\min}$ was depressed by as much as 25 °C in some mid-latitude regions, but $T_{\min}$ was within 1–2 °C of modern levels in most regions of eastern Beringia.

In New Zealand, collections of the modern beetle fauna are not sufficiently complete to allow species' climate envelopes to be constructed. As discussed elsewhere in this encyclopedia, Marra and colleagues have developed an alternative method, called the maximum likelihood envelope, that has allowed them to successfully reconstruct late Pleistocene climates. In Australia, [Porch \(2010\)](#) has developed another alternative approach, using bioclimatic envelopes to model both temperature and precipitation history. Another regional variation on the MCR method has been developed by Russian scientists, working on northeastern Siberian fossil beetle assemblages. They argue that certain plant-feeding beetle species should be included in MCR reconstructions, because they feed on plants such as sedges and mosses that remained ubiquitous in Siberia throughout the Pleistocene. Hence there should be no problem with plant migration lag under these circumstances ([Sher et al., 2005](#)).

Multifaceted Paleoenvironmental Reconstructions

The order Coleoptera is the most diverse group of organisms on Earth, with a known modern fauna exceeding 1 million species. This number is roughly four times that of all the flowering plant species (angiosperms), and more than 200 times the number of all mammal species. This incredible diversity carries through to Quaternary beetle faunal assemblages, which often contain between 100 and 200 species from dozens of families. While predators and scavengers provide reliable information on past climates, plant-feeding species serve as proxies for the reconstruction of past plant communities, and can provide such information as the relative maturity and health of forest stands, and the presence of downed, rotting trees and associated fungi. In some cases, fossil beetle evidence may provide 'smoking gun' evidence for an environmental change. Such was the case when fossil remains of the elm bark beetle, *Scolytus scolytus*, were found in British sediments that date to the time of the elm decline in the mid-Holocene. The decline may have been due to Dutch elm disease Dutch elm disease, which is transmitted by the beetle ([Girling, 1988](#)).

Lacustrine aquatic beetles provide useful information on the temperature, trophic status, substrates, and size of lakes and ponds. Stream-dwelling beetles provide information on

the size and velocity of streams, as well as temperature, trophic status, substrates, and degree of water clarity.

As in other macrofossil studies, the 'story' obtained from fossil beetle assemblages is a local one, and needs substantiating with numerous regional replicates to produce a valid paleoenvironmental synthesis. But because of the ubiquity of fossil beetle preservation in water-lain deposits, such regional syntheses are relatively easy (if time consuming) to perform.

Other Types of Studies

In addition to straightforward paleoenvironmental reconstructions, Quaternary beetle assemblages have also been used to shed light on various aspects of biological and environmental history. Beetle species longevity, combined with our ability to identify the species of many fossil specimens, allows us greater understanding of how these animals have dealt with the vicissitudes of Pleistocene environmental change.

Zoogeography

One application of fossil beetle data has been for zoogeographical studies. By plotting the shifts of beetle distributions through time and space, researchers have been able to reconstruct at least partial zoogeographic histories of various species. These studies have reinforced the theory that beetles have shifted their ranges repeatedly, and sometimes on very large spatial scales, in order to find regions of suitable climate. Such was the case for the tiny rove beetle, *Micropeplus hoogendorni*. As discussed elsewhere in this encyclopedia, this species was initially thought to have become extinct in the Pliocene or early Pleistocene, because it was only known from a 5.7 My-old deposit in Alaska. However, Coope found middle Pleistocene specimens of this beetle in Britain, and it has recently been found to be synonymous with a Siberian species, *M. dokuchaevi* (Elias, 1994).

The history of comings and goings of various groups of beetles across the Bering land bridge have been discussed by Elias et al. (2000), and the late Pleistocene and Holocene zoogeographic history of Chihuahuan Desert beetles was analyzed by Elias (1992). The fossil evidence used to develop these histories frequently disproves zoogeographic theories based solely on modern distributions (Elias, 1994). Fossil beetle evidence documents the importance of glacial refugia in maintaining high latitude faunas through glacial periods. Beringia was the most important refugium of the cold-adapted fauna in the Arctic. At the other end of the world, the beetle evidence suggests that ice-free regions of the Chilean coast formed a refuge for the cold-adapted fauna of South America.

Environmental Archaeology

There are two types of fossil beetle studies done in aid of environmental archaeology. The first is the reconstruction of natural environments associated with archaeological sites. This kind of work has mainly been done in North America, where prehistoric human populations were mainly hunter-gatherers who had relatively light impacts on the landscape. With a few

notable exceptions, these peoples built no permanent buildings, so they did not create any anthropogenic environments that attract warmth-loving insects incapable of surviving winter climate out-of-doors. This line of research is discussed elsewhere in this encyclopedia. This kind of research has also been applied to Paleolithic sites in Britain, where fossil beetle assemblages have shed light on middle and late Pleistocene environments were experienced by *Homo erectus* and *Homo neanderthalensis*.

The other type of environmental archaeological studies done with beetle (and other arthropod) remains concerns the reconstruction of anthropogenic environments, the houses, barns, and other man-made buildings where warmth-loving insects live as uninvited guests. This type of research is most common in Europe, where large-scale human disturbance of landscapes began by at least the beginning of the Bronze Age. In fact one of the difficulties of middle and late Holocene beetle studies in Europe is the inability to tease apart natural environmental change from anthropogenic change. This line of research is discussed more thoroughly elsewhere in this encyclopedia.

Emerging Research Areas

Great strides have recently been made in the study of the ratios of stable isotopes of hydrogen and oxygen in fossil insect chitin. As discussed above, chitin gives strength and rigidity to insect exoskeletons. In beetles, the exoskeleton forms as the adult insect emerges from the larva. As a long-chain nitrogenous polysaccharide molecule (a complex of sugar molecules and nitrogen), chitin incorporates both hydrogen and oxygen atoms in its matrix during formation. These atoms come from the environment – either through food eaten by the larva, or, in the case of water beetles, directly from the water in which the beetles live. As discussed in Gröcke et al. (2010), a series of modern studies have shown that the isotopic signature of hydrogen and oxygen in chitin (i.e., the deuterium-hydrogen (D/H) ratio and the ratio of ^{18}O - ^{16}O) closely matches the isotopic signature of precipitation in the regions where the beetles live. Furthermore, there is good evidence that once chitin molecules form, they are chemically inert. They do not exchange atoms (including hydrogen and oxygen) with the surrounding environment, either during the insect's lifetime, or after death.

The relationship between the D/H ratio of chitin and the D/H ratio of meteoric water in the organism's habitat has been demonstrated by several studies, using ladybird beetles (Coccinellidae) and beetles from various families (Miller et al., 1988). The hydrogen isotope composition of environmental water varies widely and systematically across the globe, and a strong and well-understood correlation exists between temperature and D/H ratios in precipitation (Rozanski et al., 1993). Because water is a key constituent of many chemical reactions in organisms, the isotope signature present in local environmental water is transferred to organisms that live in it. Because of the chemical stability of chitin, aquatic insects such as water beetles 'lock' this isotope signature in their exoskeletons. In lakes where evaporation is limited and water is in isotopic equilibrium with precipitation, water beetles thus record the isotopic signature of precipitation at the time of chitin synthesis (Gröcke et al., 2006), which makes water beetle chitin a

valuable source of climatic information. Because of its longevity in the fossil record, chitin can therefore provide scientists with an extremely powerful proxy for the reconstruction of ancient terrestrial climates.

Midge (Chironomidae) fly larvae are also aquatic, and recent studies have used stable isotope ratios from fossil midge larval remains to reconstruct past temperatures in Arctic lakes. Wang et al. (2009) demonstrated that about one third of hydrogen in chironomid larvae chitin is derived from the water in which they live. These results were obtained from laboratory studies using cultured specimens. Comparable culturing studies will need to be done to test this relationship in water beetles. Thus far, only a handful of studies have attempted to use isotopic data from insect exoskeletons to reconstruct climate (Gröcke et al., 2006; Miller et al., 1988; Wooler et al., 2004, 2008). Interest in this topic is likely to increase as more detailed knowledge of the geographic distribution of D/H from precipitation becomes available, and as advances in mass-spectrometry facilitate the rapid analysis of small samples. Much work still needs to be done to improve the methodology. For instance, more needs to be known about the influence of trophic levels, water loss, and food-derived water on D/H values of beetle chitin. Such studies have been done for laboratory-raised chironomids (Wang et al., 2009); these should also be undertaken on beetles.

Ancient DNA

In recent decades the study of ancient DNA, or aDNA, has been revolutionizing our view of the genetic history of many species of plant and animals. Ancient DNA is recovered using the polymerase chain reaction (PCR). This is a key technique in molecular genetics that permits the analysis of any short sequence of DNA without having to clone it. PCR is used to reproduce (amplify) selected sections of DNA. PCR makes a large number of copies of a gene. This is necessary to have enough starting template for sequencing. Sequencing is the process of determining the order of DNA nucleotides in a gene.

As discussed more fully in Elias (2010), the study of ancient DNA from Quaternary beetle remains began with Reiss' (2006) study of fossil insect DNA from the American Southwest. Thus far, aDNA studies from insects have focused either on late Holocene fossils, or on fossils preserved in permanently frozen sediments, or in extremely arid conditions, such as packrat (*Neotoma*) middens from the American Southwest. Both of these extreme environments tend to preserve DNA strands over long periods of time. Molecular genetic studies of fossil assemblages have the potential to test the widely held assumption (based on external morphology) that most, if not all beetle species have remained intact for hundreds of thousands (and in some cases, millions) of years (Coope, 1978; Elias, 1994).

In the study by Reiss (2006), mitochondrial DNA (mtDNA) was extracted from fossil beetle specimens identified by the author from his work in the Big Bend region of Texas. The fossils came from a packrat midden dated 23 900 cal years BP, and included fossil elytra from the weevil genus *Ophryastes*, the ground beetle genus *Harpalus*, and the dung beetle genus *Onthophagus*. After an initial failure to obtain aDNA from these specimens, Reiss eventually succeeded in getting a 316

base pair (bp) fragment from the fossil ground beetle (*Harpalus*) specimens.

Willerslev et al. (2007) demonstrated that aDNA preserves well in permanently frozen conditions. They investigated aDNA from samples of silt-rich ice taken from the Dye 3 and GRIP ice cores from Greenland, as well as from sediments sampled from the Kap København formation in northernmost Greenland. They obtained small fragments (97 bp) of mtDNA from the Dye 3 core samples, associated with the cytochrome oxidase I (COI) gene. The most reliable indication of insect mtDNA in the study was associated with Lepidoptera (moths and butterflies). Less substantial evidence was found for the recovery of COI gene sequences associated with beetles, flies, and spiders. Interestingly, no macroscopic remains of any of these arthropods were recovered from the ice-core samples, only their ancient DNA. Willerslev et al. estimated that their samples are between 800 000 and 450 000 years old, although they could not rule out a much younger age from the last interglacial interval (marine isotope stage (MIS) 5e). The Kap København sediments, thought to date from 2.5 to 2 Ma, failed to yield any identifiable fragments of DNA.

King et al. (2009) extracted aDNA from grain weevil (*Sitophilus granarius*) fossils from waterlogged archaeological sites in England. They selected six fossil specimens for aDNA extraction, and reported successful extraction of mtDNA from five of the six specimens. The modern and medieval specimens yielded fragments of various lengths from the COI gene. Two out of three Roman-age specimens yielded aDNA, but only shorter (98 bp) fragments of the COI gene.

The author is currently collaborating with Ian Barnes and their graduate student, Peter Heintzman (School of Biological Sciences, Royal Holloway, University of London), in a study to extract and analyze aDNA from fossil beetles. This will allow for a detailed assessment of phylogeographic and taxonomic questions, which cannot be elucidated by analysis of morphology alone. This work focuses on fossil specimens preserved in late Pleistocene and Holocene permafrost deposits in Alaska and the Yukon, in addition to recent (mostly twentieth century) North American museum and wild-caught specimens. Thus far, work has focused on the ground beetle *Amara alpina*, with fossil specimens originating from deposits dated from >60 000 to <7000 cal years BP. A 569 bp sequence fragment of DNA from eight overlapping fragments within the mitochondrial COI gene was targeted. Using existing sequence data from previous experiments and the literature, novel species-specific primer pairs were developed to ensure an accurate fit to primer-binding sites. Following this optimization, amplification has been successful for all of the wild-caught ($n = 13$) and 28 of the 30 (93%) museum samples tested (Figure 10). The rate of DNA recovery from late Pleistocene and Holocene samples, determined by the retrieval of at least one sequence-verified fragment, has been lower at 20% (10 of the 51 samples tested). Although this success rate is far lower than the majority of late Pleistocene, permafrost-preserved mammal bone, it is comparable to nonpermafrost late Pleistocene material. Interestingly, the success rate for aDNA extraction in these fossil specimens does not appear to be related to the age of the fossil (Table 1). One might expect that younger fossil specimens would yield more aDNA than older fossils, but successful aDNA extraction (Figure 11) was accomplished using specimens ranging from

Figure 10 Modern specimen of the ground beetle *Amara alpina*, from the Canadian National Collection of Insects, Ottawa, Ontario. One hind leg per specimen was removed for the extraction of DNA. Photograph by Peter Heintzman, used with permission.

Table 1 aDNA extraction success rates for fossil specimens of *Amara alpina* from Alaska and the Yukon, compared with fossil age

Fossil age (years BP)	Specimen	Successful aDNA extraction?
6000	A	Yes
6000	B	No
8000	A	No
20 000	A	Yes
20 000	B	No
30 000	A	No
35 000	A	No
42 000	A	No
42 000	B	Yes
55 000	A	No
>60 000	A	Yes
>60 000	B	No

Figure 11 Extraction of ancient DNA from fossil beetle specimen, School of Biological Sciences, Royal Holloway, University of London. Photograph by Peter Heintzman, used with permission.

>60 000 years BP to the mid-Holocene. Perhaps the post-mortem history of each beetle specimen plays the most important role in DNA preservation. For instance, if a beetle dies during the peak of the summer season and its body spends some weeks exposed to the air before it becomes buried and incorporated into permanently frozen sediments, then decomposition will have progressed to the point where the beetle's DNA has seriously degraded before burial. If, on the other hand, a beetle dies in autumn and its body is almost immediately frozen, then the odds of DNA preservation are greatly improved.

Given their considerable abundance, there is great potential for the use of aDNA to address phylogeographic and taxonomic questions using the permafrost-preserved remains of beetles. This aspect of Quaternary Entomology promises to shed light on the population structure and past movements of populations. Thus, it may be required to begin to study the beetles themselves, rather than only employing their presence in fossil assemblages as a proxy for reconstructing environmental change.

Introduction

During the past 30 years, Quaternary insect paleontologists working in the northern high latitudes have had the opportunity to study extremely rare deposits of fossil insects that date back millions of years. In some cases, these fossil assemblages represent Late Tertiary environments that preceded the earliest glaciations of the Quaternary. Other assemblages represent Early Quaternary environments, when glacial–interglacial cycles were beginning. These fossil assemblages afford us rare glimpses into the history of the Arctic and subarctic regions, during periods when regional environments were startlingly different from today. In many cases, there are no modern analogs for the fossil assemblages. The challenge for insect paleontologists has been to make ecological sense of these fossil assemblages, to reconstruct the environments in which they lived. It has been difficult, painstaking work that, in some cases, required decades of research to bring to completion.

These fossil insect faunas bridge a paleontological gap between the actual exoskeletal remains preserved in the unconsolidated sediments of the Pleistocene, and the mineral replacements and trace fossils preserved in deposits of bedrock, dating from the Tertiary back to the Paleozoic. What makes these Late Tertiary and Early Quaternary fossils unique is that they are millions of years old, yet they are essentially the same kind of exoskeletal remains found in much younger (Pleistocene and Holocene) sediments. In other words, these fossils are not mineralized replacements of insect exoskeletons, but the exoskeletons themselves, preserved in frozen deposits since their death. When removed from their frozen sedimentary matrix, these fossils have the same freshness of appearance as much younger specimens from other parts of the world. To the insect paleontologist studying these specimens under the microscope, it appears as if these insect specimens have spent up to several million years in a state of suspended animation. Together with frozen plant remains and vertebrate animal bones from these deposits, the Arctic insect fossils preserved from Late Tertiary and Early Quaternary deposits provide a treasure trove of information on the deep history of the Arctic regions.

History of Late Tertiary/Early Quaternary Insect Fossil Studies

The existence of these fossil deposits was unknown until quite recently. Paleontological investigation of remote Arctic and subarctic regions only came about in the latter half of the twentieth century. These studies require lengthy field expeditions that are logistically difficult and expensive. The possibility of fieldwork in such regions is generally limited to a brief summer season. Much of the research has been carried out under the auspices of governmental organizations, such as the geological surveys of Canada and Denmark, and the Academy of Sciences of the former Soviet Union. However, some of

the work has been done by governmental organizations in cooperation with universities, such as the research done by Sergei Kiselev (Moscow State University, Russia) and Svetlana Kuzmina (now at University of Alberta, Canada).

One of the most difficult aspects of this research has been establishing the chronologies of the fossil assemblages. While radiometric dating has been used to establish the age of a few samples (notably the Lava Camp assemblages from Alaska), most of the assemblages discussed below have only been dated on the basis of site stratigraphy. Many sites in Siberia have been reliably dated on the basis of the biostratigraphy of their large mammal and rodent fossils; the great antiquity of many sites provides the possibility of assessing evolutionary changes in the insect faunas. Nevertheless, the insect assemblages discussed here necessarily have only approximate age estimates. The ages discussed below represent the most up-to-date interpretations of the site investigators, but these chronologies are very likely to change in future, as more geologic research is done in the study regions.

Preservation of Late Tertiary/Early Quaternary Insect Fossils

Exoskeletal remains of insects from the Late Tertiary and Early Quaternary have been found almost exclusively in Arctic and subarctic regions. Chitin, the main structural constituent of insect exoskeletons, is highly resistant to decay, but eventually it decomposes, especially when exposed to air. The long-term preservation of chitinous exoskeletons in the high latitudes is greatly facilitated by permanently frozen ground, or permafrost.

Importance of Permafrost

Permafrost is key to the preservation of insect exoskeletons in the Arctic and subarctic, for several reasons. First, it greatly retards the pace of chemical reactions and bacterial decomposition, allowing chitin to remain virtually unaltered for as much as several million years. Second, permafrost protects insect exoskeletal remains from the physical abrasion that often takes place as sediments are reworked by wind, water, and gravity. Layers of frozen sediments tend to remain intact, or only are moved as large blocks, in response to thermokarst action (the melting of frozen sediments, leading to erosion and slumping). Thus, the frozen sediments of the North have entombed insect exoskeletons, and have protected them from the physical and chemical degradation that breaks down chitin in other types of environments.

One topic currently being explored is the recovery of frozen DNA samples from insect fossils preserved in frozen sediments. It has recently been demonstrated that frozen sediments in Siberia, Alaska, and Canada can yield well-preserved fossil

DNA from plants and mammals (Shapiro et al., 2004; Willerslev et al., 2003). It would appear likely that the frozen soft tissues of fossil insects or the frozen sediments themselves will also yield ancient DNA. If it can be obtained, this DNA will be able to help entomologists work out the genetic history of insect species in the past few million years.

Rarity of Fossil Localities

Although fossil insect impressions in bedrock and insect remains trapped in fossil amber dating back many millions of years, fossil sites containing actual exoskeletal insect remains more than 1 My old are quite rare. Permafrost environments only occur in the high latitudes, and many high latitude regions in America and Europe were repeatedly glaciated in the Quaternary. Siberia had a different situation: many ice-free regions in the high latitudes, but a lack of deposits older than the middle Pleistocene. Glaciers and ice sheets have obliterated underlying (Late Tertiary and Quaternary) deposits, stripping the land surface down to bedrock in many Arctic regions, and then leaving a mantle of reworked debris as their margins retreated. Thus, one of the main reasons why unconsolidated, organic-rich deposits of Late Tertiary and Early Quaternary age are rare is that they could only ever occur in regions that were not subject to repeated Quaternary glaciations. However, there were some regions in the Arctic that remained unglaciated through much if not all of the Pleistocene. Chief among these was the region known as Beringia, which included the unglaciated lowlands of northeastern Russia, Alaska, and the Yukon Territory, linked together by the Bering Land Bridge. This land bridge formed during glaciations, as the growth of continental ice sheets trapped huge quantities of water, causing global sea level to drop. The continental shelf regions of the Bering and Chukchi seas are relatively shallow (most of the shelf regions are less than 90 m below modern sea level), so these shelves became dry land during glaciations, connecting northeastern Siberia with western Alaska.

Types of Insects Preserved in Frozen Sediments

By far the most abundant and diverse group of insects preserved in these deposits are beetles (Coleoptera). The beetle families most often found in these ancient assemblages are ground beetles (Carabidae), water beetles (Dytiscidae and Hydrophilidae), rove beetles (Staphylinidae), leaf beetles (Chrysomelidae), and weevils (Curculionidae). Some small families are represented by very numerous remains, including pill beetles (Byrrhidae) of the genus *Morychus*, and small carrion beetles (Leiodidae). Various kinds of flies (Diptera) have been found, especially nonbiting midges (Chironomidae), but the traditional method of laboratory screening misses most of these small fossils. The pupal cases of flies are sometimes preserved. Parasitic wasps and ants (Hymenoptera) are also commonly found. Finally, several families of other kinds of arthropods, such as oribatid mites (Arachnida: Oribatida) are found in these fossil assemblages. Oribatids are soil-dwelling mites that are the chief agents of organic decomposition in Arctic soils.

The fossil insect faunas of Late Tertiary and Early Quaternary age from North America and Greenland comprise 437 taxa of insects and arachnids. Of these, 180 have been

identified to the species level (Matthews and Telka, 1997). Siberian faunas were studied without arachnids, parasitic wasps and flies (Kiselev, 1981; Kuzmina, 1989). Insect faunas of this age have also been published from northeastern Siberia by Kiselev (in Kiselev and Nazarov, 2009). These include 139 beetle, 3 ant, and 2 bug taxa, of which 119 species have been identified. Surprisingly, there are only ten species in common between the Siberian and North American/Greenland faunal lists for these ages of fossil assemblages.

Research in Alaska and Canada

John Matthews, Geological Survey of Canada, has studied a number of fossil insect assemblages of Late Tertiary and Early Quaternary age in Alaska and northern Canada, and his work has undoubtedly made the greatest contribution to our knowledge of insect faunas of this age. His work in this topic spans 25 years and 19 publications. Nine faunal assemblages dating from about 5.7 to 1.8 Ma have thus far been analyzed (Table 1). The sites range from just south of the Arctic Circle at the Lost Chicken site, to north of 80° latitude at the Meighen Island and Wolf Valley sites. Several new sites in Alaska and the Yukon that are of early Pleistocene age have been studied by Kuzmina, but have not yet been published.

The series of fossil insect assemblages (Figure 1) from these sites document very warm, generally maritime Late Tertiary climates. The insect faunas of this age are quite mixed, in terms of their modern ranges. Some of these species live today only in Asia; others live today in the temperate regions of eastern North America. As might be expected for such warm-adapted insect faunas, there is considerable taxonomic diversity in these assemblages. The level of diversity declined during the onset of climatic cooling associated with Tertiary–Quaternary transition (Matthews and Telka, 1997). The Late Tertiary faunas of the Arctic regions of North America lived in coniferous forests that were likewise more diverse than the modern boreal forests of Canada and Alaska. The ancient forests had some taxa that are less tolerant of cold climate, such as hemlocks and elderberry.

By about 2.5–2 Ma, there is reliable evidence for climatic cooling from both the insect and plant fossil records. Nevertheless, temperatures remained well above their modern levels in the high Arctic. Sites such as Wolf Valley, Ellesmere Island (2.1–1.7 Ma) and Cape Deceit, Alaska (1.8 Ma) contain mixtures of Arctic tundra and coniferous forest insect fauna and flora. The Cape Deceit fauna includes some elements that typify the mesic tundra environments that existed throughout much of the late Pleistocene, including a wide variety of ground beetle species in the *Cryobius* group of the genus *Pterostichus*. The same reconstruction has been made from the 2 Ma insect fauna from Dawson Cut Bed, Palisade site on the Yukon River, Alaska (Elias et al., unpublished).

Fossil insect assemblages of probable Early Quaternary are known from the Old Crow and Bluefish River Basins in the northern Yukon, from the Klondike gold mining district of the central Yukon, and from the Palisades site in central Alaska (Figure 2). These faunas, unlike their late Pliocene counterparts, do not contain extinct species, with the possible exception of a pill beetle (family Byrrhidae) in the genus *Morychus*

Table 1 Late Tertiary and Early Quaternary insect fossil sites

Site	Age (millions of years ago)	Insect fauna	Environmental reconstruction	References
(1) Lava Camp Mine, Alaska	5.7 ± 0.2 Ma (Late Miocene)	83 insect and arachnid taxa, including several extinct species; fauna indicative of coniferous forest	Warm, maritime climate; fossil flora includes species found today in the forests of the Pacific Northwest region	Hopkins et al. (1971), White et al. (1997, 1999), and Elias and Matthews (2002)
(2) Ary-Mas, NE Siberia, Russia	Late Miocene	31 insect taxa, including at least five extinct species; includes several North American species not found in any other Asian faunas	Fauna includes mixture of coniferous forest and open ground taxa, probably indicating open coniferous woodland or forest tundra	Elias et al. (2006) and Kiselev and Nazarov (2009)
(3) Niguanak, Alaska	Early Pliocene?	47 insect and arachnid taxa, including extinct species, <i>Diacheila matthewsi</i> . Fauna not yet fully analyzed, but has some Asian affinities	Plant fossils indicate coniferous forest, including hemlocks; climate was far warmer and less continental than today	Matthews and Telka (1997) and Elias and Matthews (2002)
(4) Ballast Brook, Banks Island, NWT, Canada	5–3 Ma	39 insect and arachnid taxa, indicative of boreal environment	Coniferous forest, similar to modern forests in the subarctic regions of Canada. There are indications that the site was near northern treeline at the time of fossil deposition. Climate substantially warmer than today	Fyles et al. (1994) and Elias and Matthews (2002)
(5) Strathcona Beaver Peat, Ellesmere Island, NWT, Canada	>3.3 Ma	86 insect and arachnid taxa, including both Arctic and boreal elements; some species with Asian affinities	Fauna and flora indicative of northern treeline setting; climate substantially warmer than today	Matthews and Telka (1997) and Elias and Matthews (2002)
(6) Meighen Island sites, NWT, Canada	3 Ma	198 insect and arachnid taxa, including both boreal and Arctic tundra species. Faunal affinities with eastern North America and Asia	Flora and fauna indicative of northern treeline environment; climate substantially warmer than today	Matthews and Telka (1997) and Elias and Matthews (2002)
(7) Lost Chicken, Alaska	3 Ma	83 insect and arachnid taxa, including blind weevil, <i>Alaocybites</i> , found today in California and the Russian Far East; boreal fauna with several extinct species	Flora and fauna indicative of coniferous forest; several warmth-loving plant species; climate with warmer winters than today	Matthews and Telka (1997) and Elias and Matthews (2002)
(8) Bluefish Basin, Yukon Territory	<3 Ma (Late Pliocene)	26 insect and arachnid taxa, including <i>Notiophilus aeneus</i> , now confined to eastern N. America, and extinct species, <i>Helophorus meighensis</i>	Bluefish plant fossil assemblages include species indicative of substantially warmer, less continental climate than exists in the Yukon today; MCR results indicate TMAX up to 3 °C warmer than today	Matthews and Ovenden (1990), Matthews and Telka (1997), and Elias and Matthews (2002)
(9) Krestovka, NE Siberia, Russia	Late Pliocene (Kutuyakh Fm.)	22 beetle taxa; mixture of boreal and Arctic fauna; some elements of steppe tundra fauna already present	Larch forest tundra landscape with steppe patches	Kiselev (1981)
	Early Quaternary (Olyorian Suite)	51 beetle taxa; most found today in Arctic tundra regions; some taxa with steppe affinities	Steppe-tundra landscape with patches of shrub tundra and coniferous woodlands	Kiselev (1981) and Kuzmina (1989)
(10) Chukochya River, NE Siberia, Russia	Late Pliocene to Early Quaternary (Olyorian Suite)	80 beetle species; most found today in Arctic tundra regions; some taxa with steppe affinities	Steppe-tundra landscape with patches of shrub tundra and coniferous woodlands	Kiselev (1981) and Kuzmina (1989)
(11) Alazea, NE Siberia, Russia	Late Pliocene to Early Quaternary (Olyorian Suite)	56 beetle species; most found today in Arctic tundra regions; some taxa with steppe affinities	Steppe-tundra landscape with patches of shrub tundra and coniferous woodlands	Kiselev (1981) and Kuzmina (1989)
(12) Sededema, NE Siberia, Russia	Late Pliocene to Early Quaternary (Olyorian Suite)	55 beetle species; most found today in Arctic tundra regions; some taxa with steppe affinities	Steppe-tundra landscape with patches of shrub tundra and coniferous woodlands	Kiselev (1981) and Kuzmina (1989)

(Continued)

Table 1 (Continued)

Site	Age (millions of years ago)	Insect fauna	Environmental reconstruction	References
(13) Palisades, Alaska	Late Pliocene	26 insect taxa including steppe-tundra and mesic tundra species; no extinct taxa identified	Both dry and mesic tundra habitats represented with TMAX 3–5 °C cooler than today	Elias et al. (unpublished)
	Early Pleistocene	27 insect taxa, all extant, indicative of northern treeline environments	Both dry and mesic tundra with some boreal elements present	Elias et al. (unpublished)
(14) Kap København, Greenland	2.5–2 Ma (Early Quaternary)	154 insect and arachnid taxa, indicative of northern treeline environments	Probably deposited after first glaciation; less faunal diversity than Meighen Island faunas, indicating climatic cooling; climates still substantially warmer than today. TMAX about 8 °C warmer than today; TMIN about 10 °C warmer than today	Böcher (1995) and Elias and Matthews (2002)
(15) Wolf Valley, Ellesmere Island, Nunavut, Canada	2–1.7 Ma	21 insect and arachnid taxa, indicative of northern treeline environments	Plant and insect fossils suggest northern treeline near site at time of deposition; climate cooler than that of Beaufort Formation faunas; TMAX 5–7 °C warmer than today	Matthews and Fyles (2000) and Elias and Matthews (2002)
(16) Cape Deceit, Alaska	1.8 Ma	86 insect and arachnid taxa, indicative of northern treeline environments; some elements of tundra fauna seen for first time in Eastern Beringian region	The vegetation record suggests that temperatures were slightly warmer than they are today. MCR results indicate TMAX about 2 °C warmer than today; TMIN similar to modern winter temperatures	Matthews (1974), McDougall (1995), Matthews and Telka (1997), and Elias and Matthews (2002)
(17) Old Crow Hidden Bluff, Bluefish Basin, Yukon	Early Pleistocene	43 insect taxa, indicative of forest but with a more significant contribution of xerophilous species (tundra and steppe) than are found here today	Tree remains suggest well-developed forest, but insect assemblage indicates high proportion of open disturbed ground and steppe patches	Kuzmina (unpublished)
(18) Klondike, Yukon	Early Pleistocene	61 insect taxa indicative of forest and boggy environment, significant numbers of mesic tundra species and some indicators of steppe-tundra	The beds yield branches and stumps of trees, smaller than recent in this area. Insect assemblage indicates climate similar to modern, but somewhat cooler and dryer	Kuzmina (unpublished)

that has not been matched with any extant species (Kuzmina et al., 2008). This beetle, and the sage-feeding weevil *Connatichela artemisiae* are not commonly preserved in these faunas. They are indicators of steppe-tundra environments that were apparently much more common in the late Pleistocene of Eastern Beringia. However, these species have been found in the Klondike fauna that is of early Pleistocene age.

Research in Siberia

The Siberian faunal assemblages of Late Tertiary and Early Quaternary age have been described from four sites, including just two of pre-Pleistocene age (Figure 3; Table 1). The sites are along the banks of large rivers (Figure 4). The oldest Western Beringian insect fauna was described from the Ary-Mas site (Figure 3). This Miocene-age fossil fauna indicates mostly riparian environments. While preservation of these fossils is generally poor, the fauna likely includes several extinct species (Elias et al., 2006; Kiselev and Nazarov, 2009).

In contrast to the fossil record of the North American Arctic, the Kutuyakh Formation Beds (Krestovka site) of late Pliocene age in northeastern Siberia already have a well-developed cold-adapted insect fauna. These assemblages include species of *Pterostichus* (*Cryobius*) spp. and *Blethisa catenaria* that live on mesic to wet tundra and forest tundra, as well as woodland species, especially weevils associated with conifers (Kiselev, 1981). Faunal assemblages from stratigraphic horizons between the Kutuyakh and Olyorian Suite Formations contain mostly tundra species, including species of *Pterostichus* (*Cryobius*) spp., as well as the more dry-adapted arctic ground beetle, *Amara alpina* (*Curtonotus alpinus* in the Russian literature). However, elements of the taiga fauna persist in these faunas, especially tree-feeding weevils. Some steppe-associated beetles made their first appearance in northern Siberian faunal assemblages of this age (late Pliocene). The combined faunal and floral evidence suggests a larch forest-tundra landscape with patches of steppe.

The Olyorian Suite is now thought to represent the early Pleistocene and part of the middle Pleistocene. Previous

attributions of this complex to the late Pliocene–early Pleistocene (Kiselev, 1981; Sher, 1974) were made on the basis of Soviet stratigraphic boundaries, in which the Pliocene–Pleistocene boundary was set at the Brunnhes–Matuyama transition of 781 000 years BP (Sher, 1997; Minyuk, 2004). Some deposits of this age are found in north eastern Siberia, especially in the Kolyma lowland region. The dominant feature of these beetle assemblages (Figure 5(a)–5(d)) is that they are virtually identical in composition to the subsequent regional faunas from Middle and late Pleistocene times. The only difference recognized thus far (Kuzmina, 1989) is that the steppe component of Olyorian Suite faunas is less important than it is in most of the middle and late Pleistocene insect assemblages. The typical Olyorian insect faunas consist mostly of tundra species, with dry tundra insects dominating over mesic and wet tundra taxa.

One very interesting site is Chomus Yuryakh is north eastern Siberia. One very large sample containing the remains of more than 5000 insects was recovered from the Olyorian Suite at this site. The fauna contained at least four extinct species: two weevils of the genus *Phyllobius* that were probably members of steppe fauna, and two species of the willow-feeding

weevil genus *Lepyryus* (Korotyaev and Kuzmina, unpublished). This is a very rare example of species extinction within the Quaternary.

Research in Greenland

Thus far, only one Greenland site has been studied that contains insect fossil assemblages in the age range being considered here. Most of Greenland has been covered by ice during the many glaciations of the Quaternary, making the fossil site all the more remarkable. Kap København (Figure 6) is the northernmost site yet studied for insect fossils of this age. It is situated near the northern tip of Greenland (Figure 3, No. 12). The fossil insect assemblages (Figure 5(e)–5(h)) have been described by Böcher (1995). The age of the deposits is estimated between 2.5 and 2 Ma, at approximately the boundary between the Pliocene and the Pleistocene. At that time, it is clear that northern high latitude climates were remarkably warm. The Kab København flora and insect fauna are indicative of northern treeline environments. It appears that the Kab København fossil beds were deposited soon after the first glacial period, near the end of the Pliocene. The Meighen Island fauna from northern Canada is more diverse, and contains more warm-adapted species than the Kab København fauna. The former fauna is thought to be 500 000–700 000 years older than the latter (Matthews and Telka, 1997).

Potential Importance of Research

The research outlined above is important to a number of disciplines. It has helped define paleoclimate reconstructions for regions that formerly had little or no reconstructions for the critical climatic transition from the relatively warm climates of the Pliocene to the oscillating glacial and interglacial climates of the Quaternary. The wealth of paleoenvironmental data extracted from the fossil insect assemblages has also added greatly to our understanding of soils, moisture conditions, and vegetation cover of the Arctic and subarctic regions during the late Pliocene and Early Quaternary. The fossil insect evidence also provides important evidence concerning the longevity of many insect species, especially beetles. Finally, the combination of plant and insect fossil assemblages has given us important new insights into the evolution, functioning, and longevity of northern biological communities.

Insects as Paleoclimate Indicators

The fossil insect research described above has demonstrated the morphological constancy of exoskeletal features in beetles and some other insects, over several million years for some species. This, alone, would seem a strong indicator that the species in question have remained constant throughout this time interval. However, insect exoskeletons provide little or no data on the internal physiology or ecological requirements of these organisms. In order to test these aspects of species' constancy, another, indirect method had to be employed. Fortunately, we do have a method of examining the ecological requirements of apparently extant species in fossil assemblages – through

the analysis of their modern counterparts. The modern distributions of species found in fossil assemblages fall within certain climatic parameters. When these parameters (such as mean temperature of the warmest or the coldest month of the year) are plotted for all the known modern collecting localities of a species, it is possible to generate a 'climate envelope' for that species (Atkinson et al., 1986). These climate envelopes vary from broad to narrow, depending on the range of thermal tolerances of the species. Elias and Matthews (2002) analyzed the climatic compatibility of the Late Tertiary and early Pleistocene fossil assemblages from Greenland, Canada, and Alaska, and in all cases the species in the fossil assemblages were found to be climatically compatible. Taking this process a step further, the climate envelopes of the species in the fossil assemblages overlapped to yield a mutual climatic range (MCR), a set of climatic parameters within which all the species in the assemblage can live.

Longevity of Insect Species

The MCR study indicates that the species in question have not evolved new sets of climatic tolerances since the Late Tertiary. Dozens of species were used in the MCR reconstructions. If this kind of physiological evolution had taken place, then it would be extremely unlikely that the climate envelopes based

on the modern distribution of these beetles would overlap to produce an MCR.

Given the fact that the modern representatives of the species in the fossil assemblages remain climatically compatible with each other, then there has either been no evolution of their thermal tolerances since the Late Tertiary, or whole suites of species have evolved new tolerances in concert with each other. The latter scenario appears extremely unlikely, as evolutionary theory holds that each species evolves independently from others.

However, as Matthews and Telka (1997) point out, the Late Tertiary beetle faunas from the Arctic also contain 'clear examples of extinct species.' It appears likely that most of these species were relatively warm-adapted, and that they failed to become established in more southerly regions during the climatic cooling that signaled the beginning of glaciations in the Quaternary. The fossil evidence demonstrates that the evolutionary 'clock' of beetles has not stopped, it is just moving extremely slowly. Some Late Tertiary species apparently were precursors to modern species that evolved during the Quaternary. For instance, Matthews and Telka (1997) discussed the possible evolutionary history of a ground beetle in the genus *Asaphidion*, an extinct species closely related to the contemporary subarctic carabid *Asaphidion yukonense*. A fossil elytron from the Lost Chicken site (Figures 1(c) and 2) clearly shows

Figure 3 Map of the Arctic, showing fossil sites discussed in text.

bare (impunctate) patches that characterize the modern species, but the patches are less well developed and elytral micro-sculpture better developed than in the extant species. Fossils that are similar to *A. yukonense* have been found in other Late Tertiary assemblages from the Arctic, but some of those have even more primitive elytral sculpture than the Lost Chicken specimens. These fossils could represent various stages in the evolution of the modern species. Matthews (1976) also described Late Tertiary fossil specimens of the water-scavenger beetle genus, *Helophorus*, which appear to be precursors to the modern species, *H. tuberculatus*. The fossils, from Lava Camp Mine and Meighen Island, exhibit more primitive elytral sculpture. Matthews traced the possible evolution of these fossil types into the extant species. Matthews (1970) also discussed the possible evolution of the more primitive rove beetles, *Micropeplus hoogendorni* and *M. hopkinsi*, leading to the modern species, *M. cribratus* and *M. punctatus*. Matthews assumed that the two former species had become extinct in the Quaternary,

but *M. hoogendorni* has subsequently been found to be extant. Modern specimens were collected from Siberia, by the Russian entomologist, Rjabukhin. Unaware of the fossil evidence from Alaska, he described the Siberian specimens as a new species, *M. dokuchaevi* (Elias, 1994). The unique example of rapid evolution in the rove beetle *Tachinus apterus* was documented by Matthews (1974) from the Cape Deceit fossil assemblages in western Alaska. The elytral proportions changed with time, together with a reduction in wing size to the point where the species became flightless. This evolutionary trend may have served as an adaptation to life in the increasing cold environments of the early Pleistocene.

Insects as Paleoecological Indicators

Some of the environments reconstructed on the basis of these insect faunal assemblages have no modern analogs, in fact, most of them cannot be found today. This does not mean

Figure 4 Fossil sites in northeastern Siberia. (a) Exposure of Olyorian Suite Formation sediments at Chukochya River; (b) Begunovskaya Suite at the Krestovka site. Photos by David Hopkins and Andrei Sher.

that the insect evidence is contradictory, it simply means that some of the ancient environments in which they lived have ceased to exist. This is especially true for the Arctic Pliocene environments. From 3 to 4 Ma, and up to parts of the Early Quaternary at Kap København, coniferous forests were growing at very high latitudes. These regions are polar deserts today, with a minimum of tundra vegetation interspersed with areas of bare rock, sand, and gravel. Paleoclimatologists have yet to develop paleoclimate models that can satisfactorily explain the existence of very warm climates in polar regions during the transition from Late Tertiary to Quaternary times, but the fossil data (plant and animal) clearly demonstrate its existence.

Origins and Longevity of Biological Communities

The fossil beetle evidence, in agreement with the fossil plant evidence from the same or similar deposits, demonstrates that biological communities are ephemeral associations of species. Certain *functional types* of communities may persist through great lengths of time (for instance, coniferous forests or Arctic tundra), but the constituent species within these communities shift with great regularity, in response to environmental changes. The Late Tertiary and Early Quaternary biota of the Arctic constituted boreal-style coniferous forests,

but these were unlike any forests that exist today, in any particular region.

One of the dominant trends in this sequence of Arctic faunas is the gradual depletion of the number of species through time. The earlier, warm-adapted faunas were relatively rich in species. The later, cold-adapted faunas contain fewer species. This makes sense from an ecological standpoint, as few insects are adapted to life in extremely cold climates. Since they do not maintain their own internal temperature through metabolism, as do mammals, insects are at a distinct disadvantage in cold climates. The modern statistics clearly reveal this pattern. Danks (1981) listed just 1800 named species of arthropods living today in the North American Arctic. The number of insect species living today in North America as a whole exceeds 90 000 species (Borror and White, 1970).

MCR Reconstructions

As discussed above, Elias and Matthews (2002) employed the predaceous and scavenging beetle species found in the Late Tertiary and Early Quaternary fossil assemblages to produce their MCR estimates (for a discussion of MCR methods, see Elias, 1994). These beetles are in various families, including ground beetles (Trachypachidae and Carabidae), predaceous diving beetles (Dytiscidae), water-scavenger beetles (Hydrophilidae), rove beetles (Staphylinidae), carrion beetles (Silphidae), and dung beetles (Scarabaeidae). Eleven fossil assemblages associated with this time interval contained sufficient numbers of identified species to yield MCR estimates. Elias and Matthews (2002) found that average winter temperatures (TMIN) in the Arctic during the latest Miocene and Pliocene were substantially warmer than they are today. The MCR estimates agree with the evidence from paleobotanical data, that Arctic Pliocene climates were far less continental than they are today. Several Pliocene-age assemblages from the high Arctic yielded mean summer temperature (TMAX) estimates 9–10 °C warmer than modern values at the sites. This is the same degree of warming required to allow coniferous forests to grow in the high Arctic. By 3 My, a cooling trend is marked in both the paleobotanical and fossil beetle evidence from Alaska. All assemblages dating between 5.7 and 2 Ma yielded TMAX values between about 12 and 14 °C, regardless of location. Thus, the insect fossil data support the theory that there was far less latitudinal gradation in temperatures during the late Pliocene than there is today. These results agree well with a study of global environments during the mid-Pliocene (Dowsett et al., 1999), which showed greatly reduced continental ice volume, greatly reduced sea-ice with the Arctic being seasonally ice free, and an expansion of evergreen forests to the margins of the Arctic Ocean. The MCR reconstructions suggest that regional climatic cooling (especially winter temperatures) began by at least 2 Ma.

The fossil insect history of the Arctic provides fascinating glimpses into a world that ceased to exist about 2 Ma – a world in which a substantially warmer Arctic was home to coniferous forests, even at 80° N, near the northernmost point of land in the Northern Hemisphere. The ecosystems of this warm Arctic zone collapsed as the Ice Ages began in earnest, but,

surprisingly, most of the insect fauna did not die out. The many species went their separate ways, some into eastern North America or southern parts of western North America, some to unglaciated regions of Beringia, others to other parts of Asia. Each species has its own unique history, its own remarkable story of survival in the face of shifting climates. Before the fossil data were published, few biologists would have guessed that 90% of the Arctic fauna of the Pliocene has remained extant to the present day. Thus, the trend of beetles shifting their ranges in response to climate change, first noted

for Pleistocene fossil assemblages (Coope, 1978), began far earlier than we might have expected.

Middle Pleistocene of Western Europe

G R Coope[†], Royal Holloway, University of London, Egham, UK

© 2013 Elsevier B.V. All rights reserved.

Introduction

Insect fossils are abundant in Quaternary deposits that have remained unoxidized since their deposition, such as ancient pond-bottom sediments, infillings of paleochannels or fen peats. Accumulations of debris in archaeological contexts also yield abundant insect remains. The most conspicuous of these fossils are fragments of Coleoptera (beetles) whose skeletons are robust and resist decomposition. Coleopteran assemblages are now known from all Quaternary periods from widespread localities in most parts of the world. Almost all the fossils show a remarkable degree of evolutionary stability so that they can be exactly matched with living species. Furthermore, there is very little evidence of global extinction of any beetle species during this period. They do, however, show abundant evidence of widespread local extinctions as the whereabouts of acceptable habitats change with time. At least on the continental masses insect species frequently responded to climatic oscillations by changing their geographical ranges, often on an enormous scale; tracking the changing locations of suitable environments sometimes for thousands of kilometers. The fact of their evolutionary constancy and their geographical mobility makes the order Coleoptera a valuable tool in reconstructing past environments and, in particular, past climates.

In recent years, the complexity of the Quaternary stratigraphy of Europe has been partially resolved by the application of a notional framework based on the marine isotope stages (MIS). In these, global fluctuations in climate, oscillating between cold and warm periods, can be recognized. It has been possible to correlate, albeit provisionally, the climatic events recorded in terrestrial sequences with the MIS sequence. However, the climatic events on land, recorded in the biotic response, may differ significantly from the marine signal. This is shown in particular by the occurrence of thermophilous taxa of both plants and animals from middle Pleistocene interglacial deposits in Britain. Using the mutual climatic range (MCR) method (Atkinson et al., 1987) on carnivorous or scavenging beetle species, it has been possible to make quantified paleotemperature estimates that are independent of those based on the macroflora. These show that the middle Pleistocene climate in Britain was sometimes warmer than that of the present day in contrast to the marine record which suggests that it was cooler globally (Candy et al., 2010).

In this article, the base of the middle Pleistocene is taken as the Brunhes/Matuyama geomagnetic boundary during MIS 19 and its upper limit as the base of MIS 5e, at the start of the Last (Ipswichian, Eemian, Wisconsinan) Interglacial. The beetle assemblages will, wherever possible, be allocated to the various MIS events. This means that several of the earlier descriptions of beetle assemblages which may well be of middle Pleistocene age will not be mentioned here because it is difficult to relate these

to the modern Quaternary stratigraphy. However, most of these early papers have been included in *A Bibliography and Literature Review of Quaternary Entomology* (Buckland and Coope, 1991).

Middle Pleistocene Beetle Assemblages

It is convenient to subdivide these middle Pleistocene interglacial beetle faunas into two groups: those that predate the extensive Anglian (Saalian) Glaciation (MIS 12) and those which postdate this major glacial event.

Pre-Anglian Middle Pleistocene Beetle Localities

Several organic deposits at the foot of the Norfolk coastal cliffs have in the past been grouped together as the 'The Cromer Forest Bed Formation.' These are now known to represent a complex sequence of interglacials that can only be provisionally attributed to any particular MIS. The deposits are highly fossiliferous and include abundant insect remains, which clearly indicate very different climates. All these deposits predate the Anglian (Saalian) Glaciation (=MIS 12). The occurrence of numerous temporary exposures of organic deposits in active gravel workings at inland localities means that the understanding of their biostratigraphy based largely on vertebrate fauna is rapidly developing. A brief summary of the more important sites will be given here but it must be borne in mind that others are currently under investigation and will be published in the near future.

Beeston

The earliest beetle assemblage from this period was obtained from deposits at Beeston, north Norfolk and can be correlated with Pre-Pastonian (West, 1980). Because they rest directly on the Chalk it is difficult to give them a precise age but they probably are equivalent to MIS 18 or MIS 20. They are possibly equivalent to the Tiglian deposits of the Netherlands. They are included here because the insect fauna is the earliest Pleistocene assemblage from the British Isles (Coope, 2000). This fauna consists of 15 taxa of which 11 could be determined to species. All are of extant species with the exception of a species of the water beetle *Agabus*, which has not yet been identified. MCR paleotemperature estimates were equivalent to northern Britain at the present day.

Broomfield

Details of the stratigraphy and paleontology of this site are given in Gibbard et al. (1996). At the moment, it is not possible to correlate these deposits precisely with any MIS event. Altogether 69 beetle taxa were recovered from the organic horizon of which 52 could be identified to species. The assemblage included a large number of species characteristic of running water and marginal riverine habitats. The discovery here

[†]Deceased.

of beetle species with southern European distributions at the present day indicates that the mean July temperature was at least 19 °C and probably a degree or so warmer than this, in other words somewhat warmer than southern England today.

Pakefield

This site has for long been known for its fossils of large vertebrates. An account of the rich beetle fauna has been recently published (Parfitt et al., 2005). The most likely correlation of these deposits is with MIS 17. Here, as at Broomfield, the fauna was characterized by numerous riverine and marsh species indicating that this deposit originated in a mature river with both shallow riffles and quieter pools in which there were submerged trunks of decomposing oak trees. The beetles indicate the presence of dried out carcasses that were partially consumed by maggots. The beetle assemblage included a number of southern European species suggesting that the climate was warmer than that of the present day. Quantified estimates of the paleoclimate using the MCR method on this beetle assemblage (Atkinson et al., 1987) indicate that the mean July temperature lay between 17 and 23 °C and that the mean January/February temperature lay between –6 and 4 °C.

Sugworth

A coleopteran assemblage has been described from a preglacial channel deposit at Sugworth near Oxford (Osborne, 1979). Again, this fauna indicates that the deposit was largely riverine. It also included several exclusively southern European species. The exclusive presence at both Sugworth and at Pakefield, of fossils of the exotic species *Oxytelus* (= *Anotylus*) *opacus*, a south eastern European species with a distribution centered on the Danube basin, suggests that both sites may be of the same age. MCR estimates on this beetle fauna indicate that the mean July temperature also lay between 17 and 22 °C and the mean January/February temperature lay between –6 and 4 °C.

West Runton Freshwater Bed

In 1995, excavations were carried out of a partial mammoth skeleton at West Runton near Cromer, north Norfolk: the type section for the Cromer Forest Bed Formation. Samples of the associated sediment were analyzed for beetle remains (Coope, 2000, 2010). The upper parts of the sedimentary sequence were devoid of any insect fossils probably due to their removal by oxidation by contemporaneous weathering. The beetles indicate a reedy marsh with any open water overgrown with the duckweed *Lemna*. Oak, elm and coniferous trees grew nearby. Of particular interest is the scarcity of dung beetles in this assemblage suggesting that the carcass may have been transported *postmortem* into its present location. MCR estimates of the climate, based on the beetle assemblage, indicate that mean July temperatures lay between 16 and 19 °C and mean January/February temperatures lay between –6 and 5 °C.

Sidestrand

About 15 km southeast of West Runton, exposures of the Cromer Forest Bed Formation occasionally outcrop at the foot of the cliff. The coleopteran assemblage includes a number of thermophilous species that were absent from West Runton indicating that the two deposits were not of the same age

(Preece et al., 2009). Here again the paleotemperatures were rather higher than in present day Norfolk.

Happisburgh 1

An organic deposit is exposed from time to time below high tide level at Happisburgh. It predates the earliest evidence of glaciation in Britain. This site also yielded a flint hand axe. The geological and archaeological contexts are given by Parfitt (2005). The insect fauna from the organic bed indicates stagnant water surrounded by a reedy marsh. It includes several species that have relatively northern distributions at the present day. MCR estimates on the beetle assemblage indicate that the mean July temperature lay between 12 and 15 °C and the mean January/February temperatures lay between –11 and –3 °C (Coope, unpublished data).

Happisburgh 3

It is important to distinguish the Happisburgh 1 locality from the nearby site of Happisburgh 3 which is older than the Brunhes/Matuyama geomagnetic boundary and therefore technically Lower Pleistocene in age. The beetle fauna from Happisburgh 3 is very rich and indicates climatic cooling from temperatures as warm as southern England today to conditions rather cooler than modern. Happisburgh 3 has produced sharp, unrolled flint flakes indicating the earliest recorded presence, so far known, of human occupation of northern Europe (Parfitt et al., 2010a).

Ardleigh

An interglacial beetle fauna has been described from middle Pleistocene deposits at Ardleigh, Essex, which is possibly equivalent to MIS 17 or 15 (Gibbard et al., unpublished). The fauna is indicative of a cool-temperate climate not much different from that in England at the present day. However, insufficient species were present to permit MCR paleotemperature reconstructions.

High Lodge

This site near Mildenhall, Suffolk, has for long been famous as a source of Lower Paleolithic flint implements. Beetle assemblages have been recovered from the organic silts which yielded a beetle fauna of 47 taxa of which 32 could be identified to species (Coope, 1992). The local environment was dominated by reedy swamp conditions. MCR estimates indicate that mean July temperatures lay between 15 and 16 °C and the mean January/February temperatures lay between –4 and 1 °C.

Waverley Wood

This site is situated south of Coventry, Warwickshire. The organic deposits were located in a series of channels directly underneath glacial deposits now attributed to the Anglian (Saalian) Glaciation. The precise age of these channels is difficult to ascertain other than that they are pre-Anglian. A large beetle assemblage was obtained from one of the lowermost of these channels (Shotton et al., 1993). The beetles indicate that sedimentation commenced in running water which later developed into a pond surrounded by a marsh. The presence of *Agonum quadripunctatus* is important because this species is attracted by forest fires and it is thus significant that charcoal

fragments occurred throughout the deposit. The climatic history during the channel filling is complex (see [Shotton et al., 1993](#), Figure 9). At the base of the Channel 2, MCR estimates indicate that the mean July temperatures lay between 15 and 18 °C and the mean January/February temperatures lay between –13 and 2 °C. However, at the top of the Channel 2 the mean July temperatures have deteriorated to between 8 and 11 °C with mean January/February values to between –25 and –10 °C. At the base of the succeeding Channel 3, temperatures had returned once again to the same cool-temperate conditions that prevailed at the base of Channel 2; evidence of a considerable climatic oscillation. A similar intense cold interlude in an otherwise temperate episode is indicated by the beetle fauna from the MIS 11 interglacial at Quinton ([Horton, 1989](#)). A struck quartzite flake in mint condition was found *in situ* within the silts of the lowest channel, indicating the presence of humans in the English Midlands living under similar climatic conditions to those outlined above.

Pool's Farm Pit

A similar beetle assemblage to that at Waverley Wood Pit has been recorded from a nearby gravel pit at Pools Farm near Brandon, Warwickshire ([Maddy et al., 1994](#)).

Mathon

This site was in the old gravel workings at The Brays Pit, near Mathon, Herefordshire, in the western English Midlands. The beetle assemblage was obtained from organic sediments at the base of the pit, underlying glacial deposits which in turn were cut into by a channel filled with interglacial deposits attributed, on palynological grounds, to the MIS 12 interglacial. The beetle fauna from the basal sediments was dominated by running water species and others that are dependent on coniferous trees ([Coope et al., 2002](#)). The climatic implications of this fauna are interesting in that one of the most abundant of these running water species, *Dupophilus brevis*, is not found today anywhere in northern regions but is confined to south-western Europe where it lives in streams that are relatively cool in summer. The conifer forest at Mathon was not therefore the strict analog of the modern boreal forests but rather resembles those of central Europe at the present day.

Coleopteran Faunas and the Possible Correlation of Middle Pleistocene Deposits

The four sites Happisburgh 1, Waverley Wood, Pool's Farm Pit, and Mathon present an interesting problem in correlation. In the absence of any evolutionary change among beetles and little evidence of global extinctions during the Quaternary, it is not possible to use the classical methodologies for paleontological correlation: it is always possible for similar assemblages to come together at different times whenever similar environments arise. Thus, gross faunal similarities do not necessarily indicate contemporaneity. However, the presence of exotic species carries more stratigraphical weight: the more unexpected the fossil occurrence of a species, the more likely it is to have stratigraphic value. The faunas from the above four sites have several exotic species in common ([Coope, 2006](#)). Perhaps the most unexpected of these is the small staphylinid species *Micropeplus hoogendorni*, a distinctive species originally

described from Pliocene deposits of Alaska that were at least 5.7 million years old ([Matthews, 1970](#)). The species was believed by Matthews to be extinct. However, this species has now been recognized as identical with the living Siberian species *M. dokuchaevi*. It is therefore interesting to note the presence in Britain of this exotic species at all four of these sites where it must have been fairly abundant. So far, this species has been found as a fossil nowhere else. The presence of unexpected species such as the above example strongly suggests that all four of these deposits are of the same age.

Coleopteran Faunas that Probably Date from Early in the Anglian Glaciation (MIS 12)

Ardleigh J, Essex

Directly overlying the Ardleigh interglacial deposits described above, was a lens of organic sediment interbedded within the gravels and named Ardleigh J. This horizon can probably be attributed to an early climatic stage of the Anglian (Saalian) Glaciation (MIS 1; [Bridgland and Allen, 1996](#)). A beetle assemblage from this deposit was dominated by high arctic species which included *Diacheila polita*, *Bembidion dauricum*, *Helophorus obscurus*, and *Holoboreaphilus nordenskiöldi*. Of particular interest was the presence also of *H. arcticus* whose modern range is in northernmost North America and the extreme northeast of Siberia in Kamchatka. This fossil occurrence is the only record of this species outside its present day range. MCR estimates based on this assemblage indicate that mean July temperatures lay somewhere between 10 and 11 °C and mean January/February temperatures lay between –14 and –10 °C.

Ostend, Norfolk

The 'Arctic Fresh-water Bed' which overlies the Cromer Forest Bed Formation was exposed for a short period at the bottom of the cliff at Ostend, Norfolk. The organic deposit was highly fossiliferous and included several arctic species of beetle including *Pterostichus brevicornis*, *P. middendorfi*, and *H. obscurus* ([Parfitt et al., 2010b](#)). MCR estimates based on the coleopteran assemblage indicated that the mean July temperature lay somewhere between 9 and 11 °C and mean January/February temperatures somewhere between –36 and –10 °C.

Brooksby, Leicestershire

Recent gravel extraction near Brooksby has exposed organic deposits filling a paleochannel, which has yielded a large coleopteran fauna that includes many cold-adapted species such as *H. obscurus*, *H. glacialis*, *Tachinus caelatus*, and *Hippodamia arctica* (Coope, unpublished data). MCR estimates based on the beetle assemblage suggest that mean July temperatures were somewhere between 11 and 13 °C and mean January/February temperatures somewhere between –17 and –11 °C. The paleochannel underlies glacial deposits of Anglian (MIS 12) age and this arctic fauna may represent an early phase of this glaciation. However, since at Waverley Wood, Channel 2 showed the gradual development of a similar cold-adapted beetle assemblage as part of a larger climatic oscillation, it is possible that the channel deposits recently exposed at Brooksby should be correlated with the terminal phase of some earlier interglacial. Of particular interest at this site is the occurrence of Paleolithic hand axes in the gravels

directly overlying the channel deposits, though as yet their exact provenance has not been determined because they were all recovered from the heap of stones rejected by the gravel company. However, as extraction progresses, definitive sections are likely to be exposed which will resolve the question of their stratigraphical context.

Early Middle Pleistocene Coleopteran Faunas and Early Lower Paleolithic Archaeology

Several of the insect faunas mentioned above are associated with evidence of early human occupation of Britain; biface hand axes and/or characteristically struck flint flakes. At some sites there were also bones that had apparently been deliberately broken open probably to extract the marrow. The beetle faunas provide intimate information about the living conditions at these times.

The fossiliferous deposits at Happisburgh 3 contain flint flakes that are the earliest evidence of human presence in northern Europe (Parfitt et al., 2010a). The beetles indicate that the people lived beside a large meandering river which occasionally inundated its floodplain. The beetle evidence also shows that the climate at that time was as warm as southern England today but, during this period of human occupation, it deteriorated to conditions at least as cold as northern Britain at the present time.

At Pakefield, on the other hand, humans occupied Britain at a time when the climate was substantially warmer than it is in Suffolk today (Parfitt et al., 2005).

At Waverley Wood at least one implement was found in place within the sediments of the lowest channel in climatic conditions not much different from those of the present day.

The sites at Happisburgh 1, and High Lodge yielded beautifully made hand axes in mint condition. The associated beetle assemblages indicate open marshland with nearby woodlands made up of both deciduous and coniferous trees, but at a time when the climate was rather cooler than that of the present day.

Post-Anglian Middle Pleistocene Beetle Assemblages

The ice sheets of the Anglian (Saalian) glacial stage covered most of the British Isles and much of north-west Europe and their deposits are relatively easy to recognize and correlate over a wide area. This event is widely attributed to MIS 12. It is convenient to use this glacial event to subdivide the middle Pleistocene insect faunas. For the most part these insect assemblages have been obtained from temperate interglacial deposits although the presence of interbedded cold-adapted coleopteran faunas at two sites toward the end of the interglacial, indicate climatic complexity.

Interglacials Correlated with MIS 11

Large coleopteran assemblages have been recorded from five sites in Britain that can be attributed to MIS 11.

Hoxne, Suffolk

This site is near the village of Hoxne in an abandoned brick pit that was, for many years famous as a source of beautifully made flint hand axes. The fossiliferous deposit is largely lake

clay. Extensive excavations have been made to investigate the archaeology, vertebrate and invertebrate paleontology and also the paleobotany of this site. At the base of the sequence, insect fossils have been obtained from the early cold phase that preceded the interglacial proper, from what may be considered as the final stage of the preceding glaciations (MIS 12) or the beginning of the Hoxnian Interglaciation (MIS 11). Beetles from a small sample of this deposit included such cold-adapted species as *D. polita*, *B. hasti*, *Oreodytes alpinus*, *T. caelatus*, and *H. nordenskiöldi*, indicating that the climate was arctic and continental (Coope, 1993).

The beetle fauna from the overlying interglacial deposits indicates still water surrounded by lush, marshy, meadow-like habitats in a mature forest of various deciduous trees, many of which were dead and decomposing. Recent investigations of the beetle faunas show that, after this temperate phase there was a return to arctic-continental conditions with the presence of exclusively arctic and Siberian species such as *H. obscurus* and *H. nordenskiöldi* (Ashton et al., 2008).

Quinton, West Midlands

Interglacial lake deposits were encountered in the construction of the M5 motorway 10 km south of Birmingham. On palynological grounds, these deposits have been equated with those from Hoxne. The insect fauna was sparse in the lower part of the sequence, but indicated warm temperate conditions somewhat warmer than those of the present day. In the upper part, where the insect fauna was richer, it showed an episode of sudden and intense climatic deterioration with the appearance of exclusively arctic-continental species such as *D. arctica*, *H. obscurus*, and *H. nordenskiöldi*. Immediately after this cold episode, a cool-temperate beetle fauna returned. This recurrence cannot be attributed to the redeposition of fossils eroded out from the earlier temperate sediments, since the earlier suite of temperate species differs considerably from those in the later temperate deposit (Coope and Kenward, 2007). This sudden and intense cold oscillation has much in common with the climatic fluctuation recognized during the later part of the same interglacial at Hoxne (see Section 'Hoxne, Suffolk').

Nechells, Birmingham, West Midlands

A sequence of beetle assemblages has been described from borehole samples through interglacial lake deposits correlated with MIS12 (Shotton and Osborne, 1965). Unfortunately, only the first part of the interglacial was represented at Nechells. Interesting members of this assemblage are southern European species that depend on trees; the weevil *Stenoscelis* (= *Brachytemnus*) *submuricatus* and the bark beetle *Platypus oxyurus* which lives exclusively on the silver fir, *Abies*.

Woodston Beds, Peterborough, Cambridgeshire

Quaternary deposits have been exposed for many years as channel-like deposits in the overburden being cleared from the Oxford clay used for brick making (Horton et al., 1992). The insect assemblage was typically interglacial and was dominated by running water species as well as indications of still or slowly flowing water, suggesting a mature river meandering across its floodplain. The likely age of these interglacial deposits is MIS 11 but here again, only the earlier part of the interglacial was represented.

Frog Hall Pit, Warwickshire

Details of the stratigraphy and paleontology of the organic deposits at Frog Hall Pit have been described by Keen et al. (1997). The beetle assemblage indicates a river meandering across a marshy floodplain flanked by oak woodland. The climate was temperate. MCR estimates of the paleoclimate indicate that mean July temperatures lay between 16 and 18 °C and mean January/February temperatures lay between –8 and 12 °C. Precipitation was sufficient to maintain a year-round flow in the river. Unfortunately, here again only the early part of the interglacial was represented at Frog Hall.

Interglacial Beetle Assemblages Correlated with MIS 9

Only three beetle faunas can be attributed to this interglacial.

Hackney, North London

A sequence of organic silts was exposed during building work at the Nightingale Estate. They yielded the only large beetle fauna that can be attributed to MIS 9. It comprised 254 taxa of which 181 could be identified to species (Green et al., 2005). These provide a complex mosaic picture of the local environment. Much of the deposit originated in a mature meandering river with shallow riffles and deeper pools. It is possible that some of the beetle species in this assemblage inhabited oxbow lakes on the floodplain. Nearby were marshes and damp meadow-like habitats frequented by large herbivorous mammals. The adjacent woodland consisted of both coniferous and deciduous trees. This assemblage includes many thermophilous beetle species. MCR estimates of the thermal climate gave mean July temperatures of about 18 °C or somewhat warmer mean January/February temperatures were between –4 and 1 °C. Here again adequate precipitation must have been available to keep the river flowing throughout the year.

Barling, Essex

During a multidisciplinary investigation, insect fossils were obtained from organic sediments filling a channel in a gravel pit on the north side of the Thames estuary (Bridgland et al., 2001). The beetle assemblage comprised 29 taxa of which 15 could be identified to species. Here again the Coleoptera indicate a riverine and swampy grassland grazed by large herbivorous mammals. Abundant Paleolithic implements have been found in the immediate vicinity. Thermophilous beetle species include the dung beetle *Caccobius schreberi*, and rotting wood beetle *Valgus hemipterus*. MCR estimates based on the beetle fauna indicate that mean July temperatures lay between 17 and 26 °C and that mean January/February temperatures lay between –11 and 13 °C.

Cudmore Grove, Mersea Island, Essex

Organic sediments occupying a broad channel-like depression are exposed at the foot of the sea cliff. A rich beetle assemblage was obtained from near the base of this sequence (Roe et al., 2009) comprising 52 taxa of which 37 could be named to species. Here, the beetles indicate slowly moving or stationary water with reedy marshes and grasslands where large mammals were feeding. Of outstanding interest in this assemblage, are beetles that depend on dead timber, such as *Osmoderma eremite*

and *Prionus coriarius*. The presence of exotic thermophilous species indicates that climate was warmer than that of the present day. MCR estimates show that mean July temperatures lay between 16 and 22 °C and mean January/February temperatures lay between –7 and 4 °C.

Interglacials Correlated with MIS 7

Five large insect faunas are known that can be attributed to this climatically complex period.

Stanton Harcourt, Oxfordshire

An account of the stratigraphy and paleontology of this site have been given by Briggs et al. (1985). The fossiliferous deposits were in a channel cut into the Oxford clay. A single 10 kg sample yielded 122 beetle taxa of which 88 could be identified to species. This fauna indicates a moderately large river with riffles and pools with bare clay banks in places and lush marshes alongside. This habitat attracted many large herbivorous mammals. Drier ground nearby was thinly vegetated with heathers and oaks. MCR estimates of the climate indicated mean July temperatures between 16 and 18 °C with mean January/February temperatures close to 0 °C. Numerous Paleolithic implements were found at this site.

Marsworth, Buckinghamshire

The complicated stratigraphy and paleontology of this site has been described by Murton et al. (2001). A beetle fauna from the Lower Channel comprised 92 taxa of which 57 could be named to species. There is a curious rarity of water beetles and a complete absence of the species indicative of running water suggesting that when the sediment was laid down the area had become a marsh surrounded by drier sandy soil. MCR estimates indicate that the mean July temperature lay between 15 and 17 °C and mean January/February temperatures lay between –9 and 1 °C.

Stoke Goldington, Bedfordshire

The stratigraphy and paleontology of this site has been described by Green et al. (1996). A beetle assemblage of 91 taxa, of which 60 could be identified to species, was obtained from the deposits in the 'lower channel.' This assemblage indicated very slowly moving or stationary water with much swamp vegetation, notably the sweet grass *Glyceria*, which is attractive to herbivorous mammals, notably abundant mammoths. The beetle assemblage indicates similar climatic conditions to those at Marsworth.

Upper Strensham, Worcestershire

Organic deposits were encountered in a temporary exposure together with numerous mammoth bones (De Rouffignac et al., 1995). The associated beetle assemblage comprised 119 taxa of which 79 could be identified to species. They indicate that the sediment accumulated in a pond surrounded by meadow-like habitats. In spite of the apparent rarity of trees, the beetles were entirely temperate, suggesting that the mean July temperature was about 16 °C and mean January/February temperatures were about 0 °C.

Aveley, Essex

Temporary exposures near Aveley, Essex, have attracted attention because of the occurrence of mammalian bones. These deposits are now generally accepted as being of MIS 7 age. Associated organic sediments have yielded large insect faunas (Schreve et al., in press). They indicate an extensive marsh with adjacent grassland and oak woodland. The climate was temperate. MCR estimations based on the beetle fauna indicated that mean July temperatures lay between 17 and 18 °C and mean January/February temperatures lay between –2 and 0 °C.

Cold Stage Correlated with MIS 6

Balderton Sand and Gravel Formation

Terrace deposits of the river Trent between Newark and Lincoln have, on geological grounds, been equated with MIS 6 and are associated with a cold stage mammalian fauna. At several sites, organic sediments near to the base of these gravels have yielded a beetle assemblage that included numerous exclusively arctic-continental species (Brandon and Sumbler, 1991; Coope and Taylor, 1991). These included *D. polita*, *D. arctica*, *H. obscurus*, *H. sibiricus*, *H. jacutus*, *Boreaphilus henningianus*, and *T. caelatus*. The local environment was reminiscent of tundra. MCR estimates based on the beetle faunas indicated that the mean July temperature lay between 10 and 13 °C and the mean January/February temperatures lay between –25 and –12 °C.

Middle Pleistocene Coleopteran Studies in Western Europe

Two important middle Pleistocene coleopteran assemblages have been described from Western Europe. Firstly, from interglacial deposits at Dingé, in northwest France, a large beetle assemblage has been described as part of a multidisciplinary study (Andrieu et al., 1997). This fauna indicative of a warm temperate climate, is believed to date from MIS 7 or 9. Secondly, an extensive insect assemblage has been described as part of a multidisciplinary study from interglacial deposits at La Côte in the western French Alps that probably date from MIS 11 (Field et al., 2000). The wealth of paleoecological data that is emerging from these investigations of coleopteran assemblages points to exciting new opportunities throughout western Europe for reconstructing past local environments and also for giving quantified estimates of past climatic conditions.

Conclusion

The sequence of coleopteran assemblages outlined above provides an ecological picture that is consistent with the other physical and biological environmental indicators. Thus, the fossil beetle assemblages show constancy in their environmental requirements as well as stability in the morphology of their component species. Using the MCR method, it has been possible to quantify climatic parameters for both interglacial and glacial events. In particular, many middle Pleistocene

interglacial faunas from Britain include southern European species indicating that the climate was substantially warmer at those times than it is at the present day. During the intervening cold periods, the presence of exotic cold-adapted beetle species in Britain showed that the climate was of arctic and extreme continental severity. In stratigraphical correlation, the presence of unexpected exotic species in assemblages may provide better indicators of similarity of age than their gross faunal (or floral) similarity.

Late Pleistocene of Australia

N Porph, Deakin University, Burwood, VIC, Australia

© 2013 Elsevier B.V. All rights reserved.

Introduction

Like other parts of the Southern Hemisphere, the history of research into late Quaternary beetle records in Australia is relatively short. This stems from a range of factors including the dominance of pollen analysis in exploration of Quaternary climates and environments, a longstanding lack of interest in alternative proxies, the difficulty of developing new proxies to modern standards and, perhaps especially, the relative lack of knowledge regarding the modern Australian beetle fauna (see below). This last factor applies to other regions of the Southern Hemisphere but is extreme in Australia because of the massive size of the fauna. Nonetheless, within this context significant advances have been made in terms of methods for the reconstruction of climatic parameters (Porch, 2010) and in the application of these methods to the Quaternary record (Porch, 2006; Porch et al., 2009; Sniderman et al., 2009). This article presents an overview of the current state of Quaternary beetle analysis in the Australian context, focusing on records from the late Quaternary.

The Australian Beetle Fauna

With a described beetle fauna of about 24 000 species (Lawrence and Britton, 1994) and an estimated fauna that may include 80–100 000 species, the Australian beetle fauna is large by world standards (Yeates et al., 2003). Indeed, it is likely that the Australian fauna contains at a minimum of 10 times, and potentially 20 times, as many species as Great Britain. In this context, it is sobering to note that there are almost as many *genera* of beetles in Australia as there are *species* in Great Britain and that some large Australian genus level radiations (such as the genus *Castiarina* Gory & Laporte (Buprestidae) and the genus *Heteronyx* Guérin-Ménéville (Scarabaeidae)) may individually contain the equivalent of around 10% of the British fauna. Special aspects of the Australian fauna include a number of large radiations associated with the dominant sclerophyll flora and many examples of taxa exhibiting 'southern connections.' These are taxa, usually at the level of genus or above, with relatives in parts of the former Gondwanaland (New Zealand, South America, New Caledonia and to a lesser extent, Southern Africa). These issues are reviewed for the Australian invertebrate fauna by Austin et al. (2004).

Given these difficulties in understanding the Australian fauna, it may seem that analysis of Quaternary assemblages would be intractable, but fortunately there are a number of factors that work in favor of a Quaternary entomologist. First, there are a number of important groups that are, in contrast to much of the fauna, well to very well known taxonomically and to a lesser extent ecologically. These coincidentally include

some of the key taxa utilized in Quaternary entomology in regions where it is well established (e.g., Scarabaeidae: Aphodiinae, Scarabaeinae; Dytiscidae; Hydrophilidae; Hydraenidae; and, some groups of Carabidae). Second, many groups that may not be well known systematically are well collected and represented in museum collections, reflecting the high level of interest in the nature and composition of the Australian fauna. Finally, there are methods available that can extract high-quality climatic data from the distributional data stored in collections and the literature. These methods are explored in the following section.

Paleoclimatic Reconstruction

Methodological Context

Bearing in mind the limitations noted above, it is obvious that an approach equivalent to that taken in regions of the Northern Hemisphere, where Quaternary beetle assemblages are typically examined, is untenable in the Australian context. The lack of specific ecological data for many taxa limits the detail of environmental reconstruction that may be attempted and the smaller amount of collection data (e.g., number of locality records) has meant that an approach like the mutual climatic range (MCR) method so commonly used in Europe and North America was unlikely to be of much use here. This is because the MCR method implicitly assumes that the climatic distribution of each taxon is well known, something reasonable in regions with a long and intensive history of taxonomic, ecological, and distributional research. In the Australian region, alternative methods have been developed that take into account how the climatic significance of an individual taxon is affected by the quality of its collection data. Marra et al. (2004) came to similar conclusions in New Zealand and developed the maximum likelihood envelope (MLE) method for estimating the likely climatic range for each taxon in fossil assemblages from that country.

The Coexistence Approach to Paleoclimatic Reconstruction

Details regarding the approach for quantification of past climatic parameter values can be found in Porch (2010). A summary of the approach and comment on potential limitations of the method are presented here. All recent methods of reconstructing Quaternary paleoclimates using fossil beetle assemblages utilize methods that rely on climatic coexistence, that is, the overlap of climatic ranges of the species in the assemblage (Kershaw and Nix, 1988; Mosbrugger and Utescher, 1997). This approach does not rely on the actual coexistence of species in geographic space but on their potential coexistence based on the climatic requirements of individual species (Figure 1) – it takes no account of other potential factors that

Figure 1 Reconstructing parameter values: an example using ‘temperature of the warmest quarter’ for a modern assemblage of 14 aquatic beetles from northern Australia (after [Porch 2010](#)). Species in the assemblage are listed (taxon) at the left side of the figure along with the number of geocoded localities (records) that contribute to their bioclimatic profile. Box-plots summarize the range of values for each taxon. The left figure (RAW) shows the raw values based exclusively on the range of values in the bioclimatic profile whilst the figure on the right (EPR) shows this range supplemented by the estimate parameter range ‘error’ (see [Porch 2010](#)). For both cases the envelope of overlap determines the range of potential values for the assemblage (26.4–29.9 °C for RAW and 25.3–30.9 °C for EPR) and the mid-point the predicted value for comparison with the observed value at the collection site (see [Figure 2](#)). The EPR figure illustrates that in northern Australian assemblages the edge of Australian climate space (ACS) is reached when the error values are included limiting the ability to predict climates warmer than the present value in ACS. For this reason coexistence methods always underestimate predicted values at the warm end of ACS and overestimate values at the cold end of ACS.

determine or limit a species’ range. The dominant approach in the Northern Hemisphere MCR method relies on climatic coexistence in two dimensional thermal space ([Atkinson et al., 1986](#)), but has also been applied infrequently to a climatic space that combines thermal and precipitation values ([Elias, 1997](#)). The MLE method developed in New Zealand reconstructs single parameters individually and has been used to reconstruct both temperature ([Marra et al., 2004, 2006](#)) and precipitation values ([Burge and Schulmeister, 2007a](#)). The approach adopted in Australia ([Figure 1](#)) has many similarities to the MLE method but with some significant differences, especially in relation to the estimation of parameter errors associated with relatively poorly known taxa and validation of the approach using jack-knifed parameters based on modern assemblages ([Porch, 2010](#)).

Thus far, bioclimatic profiles have been assembled for over 1000 species of Australian beetles using data from the literature, from museum databases and collections, and from the author’s own focused collection on groups that are common in the fossil record. These bioclimatic profiles are based upon three-dimensionally geocoded locality data and produced using the ANUCLIM 5.1 computer program ([Houlder et al., 2000](#)). BIOCLIM, a program within ANUCLIM, generates estimates of up to 35 climatic parameters (temperature, precipitation, radiation, and moisture index) for each locality from which a taxon is recorded. This *bioclimatic profile* forms the basic climatic summary for each taxon, mostly species, but in some cases species groups or even genera or families. Although it is theoretically possible to estimate the value for any climatic parameter, a study of these factors has

determined that only a relatively small proportion are actually likely to be ecologically informative (see [Porch, 2010](#), for discussion).

Because the amount of geocoded collection data varies between taxa, and few taxa are extremely well known, an approach for estimating the actual bioclimatic limits (parameter range) is necessary. The approach taken in Australia utilizes the relationship between the range of values for a parameter, the number of geocoded records for a taxon, and the effect of increasing data quality on range estimation (see [Porch, 2010](#)). The efficacy of the approach was then tested by using jack-knifed data from modern assemblages to ensure that the error assessments were sufficiently broad to enable accurate climatic reconstruction under modern circumstances, a critical test of the limitations of the method (e.g., [Figure 2](#)). Results of the jack-knifed modern tests indicated that critical climatic parameters including summer temperatures and precipitation could be accurately reconstructed. [Figure 3](#) illustrates the relationship between increasing numbers of taxa contributing to an assemblage and the precision of the reconstruction. Limitations in reconstructing past climates include the potential complexity of interpreting seasonal temperature regimes under climatic conditions that do not presently exist ([Jackson and Overpeck, 2000](#)): for example, some late Pleistocene intervals in Australia saw warm summers and enhanced thermal seasonality with winter climates colder than presently exist here. This is not an issue limited to Australia or to the BIOCLIM method, but rather one that exists anywhere such no modern-analog conditions may be encountered.

Figure 2 Summary of the observed (x-axis) versus beetle-predicted (y-axis) values for the parameters ‘temperature of the warmest quarter’ and ‘precipitation of the warmest quarter’ using four ‘ecological’ assemblage types (aquatic (63), dung/saprophage (46), forest (32) and riparian (14)) and the complete assemblage – all taxa (53); (figures refer to number of modern assemblages that contribute to the observed beetle-predicted assessment). Red line is the line of equilibrium. The best fitting third order polynomial is shown for each assemblage and values of the r^2 for both linear and these third order polynomial regressions are presented. Values in boxes are for represent the minimum difference between the predicted range and observed value for assemblages that fail to overlap the observed value. Note in particular the excellent r^2 values for the temperature parameter and the sigmoidal shape of the polynomial regression representing the over and underestimated noted in reference to Figure 1, and the fact that the observed value falls within predicted range for the precipitation estimates for all assemblages.

Figure 3 The relationship between the number of taxa in an assemblage (by ecological category as per Figure 2 – see caption) and the prediction error for the parameter temperature of the warmest quarter (difference between observed and predicted value). The accuracy of the prediction increases markedly with increasing numbers of taxa represented in the assemblage to the extent that with more than 20 taxa in an assemblage the predicted value is likely to be within about 1 °C of the observed value in the majority of cases (after Porch 2010).

A Longer Quaternary Context: The early Pleistocene Stony Creek Basin Site

The remarkable site of Stony Creek Basin in southeastern Australia (Figure 4) contains 40 m of organic clay that dates to the period between approximately 1.85 and 1.55 Ma (Sniderman et al., 2007). It is incredibly rich and generally well-preserved insect assemblages (e.g., Figure 5) are associated with diverse rainforest and wet sclerophyll forest, vegetation types that no longer occur in the region (Sniderman et al., 2007). The beetle record also includes a wide range of regionally extirpated taxa, with many restricted to either warmer wet forests of the east coast of Australia or taxa that are today found in the cool wet forests of southeastern Australia. Although the Stony Creek Basin assemblages have no modern analog, paleoclimatic reconstruction implies they were deposited under a warmer climatic regime with substantially enhanced summer rainfall conditions (Sniderman et al., 2009), demonstrating that Pliocene-like climates were maintained until at least the early Pleistocene. Enhanced summer rainfall would be necessary to allow the development of wet forest and rainforest on the site today, because the modern regional climate is too dry to support either of these vegetation types. To date, only a fraction of the Stony Creek Basin insect faunal record has

Figure 4 Sites mentioned in text. late Pleistocene beetle fossil sites indicated by red dots.

Figure 5 Typical beetle specimens from sclerophyll forest assemblages of the early Pleistocene site of Stony Creek Basin. (a) Left elytron of *Pycnomerus* cf. *fuliginosus* Erichson (Zopheridae); (b) right elytron of *Saprosites* Redtenbacher (Scarabaeidae: Aphodiinae); (c) right elytron of a pselaphine cf. *Anabaxis* Raffray (Staphylinidae: Pselaphinae); (d) right elytron of *Austrorhysus* Steel (Staphylinidae: Proteininae); (e) head of *Lepanus* Balthasar (Scarabaeidae); (f) pronotum fragment of *Pristoderus* cf. *pustulosus* (Blackburn) (Colydiidae). Scale bars: (a, b) 1 mm, (c, d) 0.5 mm, (e, f) 0.5 mm.

been examined and there remains much to be learned from the unique beetle fossil assemblages from this site. The presence of a range of potentially extinct species in genera that would be considered well-known (e.g., *Stenus* (Staphylinidae); *Lepanus* (Scarabaeinae)) hints that the demise of the warm wet climates of the early Pleistocene may have resulted in significant levels of extinction as rainforest and wet forest faunas contracted to their Quaternary refuges. Given there is substantial evidence of plant extinction in early to middle Quaternary records in southern Australia (Jordan, 1997), and in the Stony Creek

Basin record specifically (Sniderman et al., 2007), this may not be surprising.

Late Pleistocene Records

Yarra Creek, King Island, Tasmania

The Yarra Creek assemblage is derived from peat and peaty sand outcropping in coastal cliffs on the southeastern side of King Island in Bass Strait between Tasmania and the Australian

mainland (Figure 4). The assemblage is considered to represent the Last Interglacial interval, and was deposited by a fast-flowing stream in a back-dune swamp (Porch et al., 2009). A less likely alternative interpretation of the thermoluminescence-based chronology may suggest the assemblage is younger than marine isotope stage (MIS) 5e but that it is certainly from MIS 5. A number of pieces of evidence, however, including the presence of coastal plants in the fossil assemblage, imply that the MIS 5a interpretation is likely to be correct.

The Yarra Creek beetle assemblage is associated with rich pollen and plant macrofossil records that include several cool temperate rainforest species that no longer occur on King Island: some like the Myrtle Beech (*Nothofagus cunninghamii*) have been absent from King Island through the Holocene. Interpretation of the paleoclimatic significance of the plant assemblage implies it was deposited under conditions of enhanced summer rainfall, one of the principal limiting factors of *N. cunninghamii*. Interpretation of the paleoclimatic significance of the beetle assemblage similarly implies that summer rainfall was higher, although estimates of thermal regimes suggest they may have been similar to present for most parameters. The only significant departure from this pattern of similar thermal regimes is for measures of temperature seasonality. Porch et al. (2009) argued this departure was an artifact of the reconstruction methodology relating to the unique, highly equable climate of King Island. The lack of collection records for many of the plants and insects from highly equable climates necessitates a reconstruction of much more seasonal climates from the assemblage-based data. There are three possible explanations. First, the modern absence of plants like *N. cunninghamii* and some of the beetle taxa found in the fossil assemblages is related to the lack of suitable summer rainfall on King Island. Second, the absence of these taxa is related to

their extinction subsequent to the time of fossil deposition (e.g., during the Last Glacial Maximum (LGM)) and their lack of ability to recolonize. Or, third, and relating to the less well-known insects rather than the plants, some or many of the taxa found in the fossil assemblages may still be present on King Island today, but their presence remains undetected.

Biogeographically, there are a number of interesting patterns in the Yarra Creek insect assemblage. These include the presence of mainland species such as *Archaeoglenes australis* Lawrence (Tenebrionidae) and *Smicrophylax* voucher species AV1 (Trichoptera) (Figure 6) that are presently unknown from anywhere in Tasmania including the Bass Strait islands. In addition, mainland taxa such as *Mecyclothorax 'cordicollis'* (Carabidae) and *Prostomis cornuta* Waterhouse (Prostomidae) have modern ranges that reach as far as the Bass Strait islands but no further. Finally, there are Tasmanian species such as *Ceratognathus westwoodi* Thomson (Lucanidae), whose modern ranges do not reach the mainland or the Bass Strait islands.

Spring Creek, Southeastern Australia

The Spring Creek site in western Victoria yielded a rich insect assemblage dominated by beetles and caddisflies. It is associated with an assemblage of megafaunal mammal species including *Diprotodon*, *Zygomaturus*, and several large extinct kangaroos (Flannery and Gott, 1984). The site has a controversial history concerning its chronology and the interpretation of its depositional history (summarized in White and Flannery, 1995). The insect assemblage is derived from bedded organic fine sands that outcrop at the margins of the creek. Radiocarbon dating of both plant macrofossils and insect remains suggest the material was deposited prior to about 45 000 radiocarbon years ago, confirming White and Flannery's

Figure 6 Insect specimens from late Pleistocene sites. (a) *Triplectides Kolenati* (Trichoptera) frontoclypeus, Pipe Clay Lagoon, Tasmania. (1995) view that the fauna dates to older than 35 000 years, based on contaminated accelerator mass spectrometry (AMS) ages on bone. Recent OSL dating of the sequence have yielded significantly younger ages (Fitzsimmons, personal communication, 2010). Three radiocarbon dates on plant macrofossils and two dates from insect remains resulted in ages consistent with an age older than the limit of the radiocarbon method, so it is likely the insect assemblage is older than 45 000 years (Porch and Kershaw 2010).

The Spring Creek assemblage is rich in aquatic insects, including a range of caddisfly taxa characteristic of warm lowland streams. Associated beetles include several species of the riffle beetle (Elmidae) *Austrolimnius* Carter & Zeck, a group restricted to well-oxygenated flowing water. Other water beetles include a range of generalist predaceous diving beetles (Dytiscidae) that are commonly found in lowland streams. The terrestrial assemblage is notable in the absence of taxa that are specifically or even frequently associated with trees. This absence parallels the absence of trees inferred from the pollen record that consistently has less than 5% tree pollen. Grass-feeding taxa such as the fungus weevil (Anthribidae) *Euciodus suturalis* Pascoe are present, but not in the numbers that occur in Holocene western Victorian basalt plains sites. The presence of the tiny metallic wood-boring beetle *Germarica* Blackburn (Buprestidae) implies the local presence of *Casuarina*/*Allocasuarina*. These genera are frequently trees, but the occurrence of abundant branch fragments belonging to a low growing *Allocasuarina* species suggests the beetle was feeding on these shrubs rather than trees of the same genus/genera.

The apparent lack of trees indicated by both the pollen and beetle records implies cold and dry conditions, at least based on the conventional interpretation of treeless vegetation in southern Australian pollen records (Kershaw et al., 1991). However, the composition of both the aquatic and terrestrial insect records completely contradicts this climatic interpretation. As noted above the caddisfly assemblage contains species such as *Archaeophylax canarus* Neboiss that are restricted to lowland habitats, especially to the east in the slightly more continental inland regions. Similarly, the terrestrial beetle assemblage is characteristic of low montane to lowland habitats in eastern Australia. Species such as the moisture-loving ground beetles *Pericompsus semistriatus* (Blackburn) and *Bembidion ateradustum* Liebherr (formerly *Bembidion blackburni* Csiki) imply conditions similar to those that occur on the site today. In terms of moisture regimes, there are several species that would require at least as much summer rainfall as today. The water scavenger beetle (Hydrophilidae: Sphaeridiinae) *Notoceryon* Hansen, although poorly known at the species level, is well collected and found in dung and moist leaf litter in forests throughout eastern Australia. Both the aphodiine dung beetles *Proctophanes sculptus* (Hope) and *Ataenius basiceps* Lea require relatively moist summer environments similar to those of *Notoceryon* Hansen. Together these and other species, and the evidence from the caddisfly assemblage, demonstrate that summer precipitation was near the present level. Thus, the lack of trees must be explained by some phenomenon other than lack of available moisture.

Pulbeena Swamp, Northwestern Tasmania

The record from Pulbeena Swamp (Colhoun et al., 1982), was the first to be examined for fossil insects in Australia. Material

from the site is unfortunately relatively poorly preserved, reflecting the combination of relatively slow sediment accumulation and the highly alkaline nature of the site sediments. Insect remains are present in several moderately humified and, in places, wood-rich peats that date to MIS 3. Younger peats that date to MIS 2 are well-humified and contain very poorly preserved insects or no insects at all. Assemblages from the MIS 3 peats include typical Tasmanian wet forest inhabitants such as the ground beetle *Promecoderus viridianeus* Sloane, abundant short-winged mold beetle remains (Staphylinidae: Pselaphinae), as well as rove beetles (Staphylinidae) in the Aleocharinae group and moisture-loving ground beetles such as *B. ateradustum* Liebherr, *Cyphotrechodes gibbipennis* (Blackburn) and a wide range of marsh beetles (Scirtidae). These assemblages occur with a range of wet forest land snail species; collectively they indicate wet conditions with temperatures that range from modern parameters to several degrees colder and at least as wet as present during the summer.

Caledonia Fen, Montane Southeastern Australia

Small numbers of beetles have been recovered from the site of Caledonia Fen at 1200 meters elevation in the Victorian alpine region (Figure 4). A continuous pollen record for the site has been published (Kershaw et al. 2007), which demonstrates that for all of MIS 3 and MIS 2 the site was surrounded by grass and herb dominated habitats. Intermittent deposits containing beetles were recovered from the 200–500 cm interval which dates between 50 and 25 ka radiocarbon years BP, based on AMS radiocarbon dates on twigs and seeds (Kershaw et al., 2007). The most common beetles in the record are the riffle beetle *Austrolimnius* Carter & Zeck and the minute moss beetle (Hydraenidae) *Tympanogaster* subgenus *Hygrotympnogaster* Perkins which occur from ~50–32 ka BP. These taxa do not occur in the immediate vicinity of the site today (a fen), but are restricted to gravel in flowing water and water-soaked rock faces, respectively. This implies that throughout the deposition of at least much of MIS 3, the site was fed by flowing streams rather than being isolated from the fluvial system of the catchment. This accords with the dominance of peat accumulation during the Holocene and last interglacial and clastic sedimentation between these periods.

Northwest Crater, Tower Hill, Southeastern Australia

Preliminary examination of LGM sections of Northwest Crater pollen cores has demonstrated the preservation of insects within the LGM part of the sequence. Samples examined (50 ml) contain very small assemblages consisting of both aquatic and terrestrial taxa. Aquatics include chironomids, caddisflies, predaceous diving beetles (*Necterosoma* Macleay, *Sternopriscus* Shapr), and water scavenger beetles (*Hydrochus* Leach, *Enochrus* Thomson, *Paracymus* Thomson). The few terrestrial taxa thus far found include rove beetles in the Quediinae group, the water scavenger beetle genus *Notoceryon* Hansen, minute brown scavenger beetles (Latridiidae) and ants. The presence of *Notoceryon* Hansen in a sample from 12.85 to 12.88 m in the sequence is significant in terms of moisture regimes. All modern records of the genus are from the moist forest habitats of eastern Australia: it is absent from

dry inland habitats that have suitable temperature regimes. Further work, using larger samples, is required to fully assess the nature of LGM climates in southeastern Australia.

Pipe Clay Lagoon, Southeastern Tasmania

The Pipe Clay Lagoon sequence outcrops in a wave-cut cliff at the edge of Pipe Clay Lagoon, a marine embayment in southern Tasmania. Colhoun (1977) described the pollen record from the site and published several radiocarbon dates that demonstrated the sequence was deposited in late MIS 3 to very early MIS 2. The sequence consists of two sandy peat beds varying from 5 to 15 cm in thickness, separated by about 5–8 cm of inorganic sand. The organic beds are set within a larger inorganic sand unit that Colhoun (1977) interpreted as wind-blown (aeolian). Examination of the two organic-rich sand beds at a single location revealed the presence of moderately well-preserved insects in the uppermost bed, and very little fossil material in the lower bed. A single AMS determination of seeds was obtained to test the original chronology of Colhoun (1977). The result ($21\,070 \pm 100$ (OZF799) on *Neopaxia* seeds) demonstrates that the upper peat bed clearly dates to the last millennium of MIS 3, about 26 000 cal BP (Porch, 2006).

The insect assemblage from the upper organic bed was relatively small and dominated by aquatic and riparian species, rather than terrestrial taxa. The species present suggest that the assemblage was deposited in relatively shallow water, perhaps with seasonally or locally variability, allowing the site to be occupied by hydrophilic taxa such as the ground beetles *Pseudoceneus* sp., *Bembidion aderustum* Lieberr and *C. gibbipennis* (Blackburn). The aquatic species in the assemblage are wide ranging taxa, except the predaceous diving beetle *Sternopriscus* spp. which may be *S. tasmanicus* Sharp, a Tasmanian endemic. Terrestrial species include specifically unidentified short-winged mold beetles and other rove beetles, the aphodiine dung beetles *A. basiceps* Lea and *Podotenus erosus* (Erichson), a Tasmanian endemic and the saproxylic (living in dead or decaying wood) cylindrical bark beetle *Pycnomerus secutus* (Pascoe).

Paleoclimatic interpretation of the assemblage implies warm summers with a range from several degrees cooler than present to the present value and increased continentality with increased seasonality, or cooler winters, at least in terms of maximum and minimum values. The presence of several taxa including *A. basiceps*, *P. erosus*, and *P. secutus* implies the precipitation estimates exceed present values for summer. *A. basiceps* is much more abundant on the mainland and has only been collected once in Tasmania, in the northeast part of the island, although the habitat of this species (wet grasslands/woodlands) has not been examined as well as wet forest habitats, so its distribution may be wider than currently recognized. On the other hand, both *P. erosus* and *P. secutus* are widespread in forest habitats today, and are commonly picked up using mass collecting techniques, meaning they are probably better known and thus provide more information regarding paleoclimate. It is clear, however, based on the nature of the beetle assemblage and the sedimentary context (the occurrence of organic sedimentation in a lowland setting), that the late MIS 3 climate was moist and cool rather than dry and cold.

Discussion

Late Quaternary Environments and Paleoclimates: Reconciling Plants and Beetles

A theme that emerges from the above review is that it is difficult to reconcile the pollen-based interpretation of treelessness as implying cold and dry conditions and the nature of insect assemblages from these sites. This aspect parallels somewhat the results of similar studies in other regions of the globe where at times there has been significant differences in the interpretation of paleoclimate based on pollen and beetle assemblages. In England, Coope and Angus (1975) noted this issue with reference to the Isleworth site where a treeless pollen assemblage was inferred to indicate tundra and cold conditions, whereas the beetle assemblage contained species indicating warm conditions. Coope (1977) argued that this reflected a lag in the vegetation response to warming conditions relative to the more vagile insects which were able to rapidly colonize suitable climatic habitat. The situation in Australia is quite different, partly as a result of the fact there was no continental-scale migration of tree species, a situation that parallels New Zealand where similar arguments about the nature of treelessness and distribution of forest during the last glacial are ongoing (Burge and Schulmeister, 2007b; McGlone et al., 2010). These arguments, however, tend to revolve around the extent of woody vegetation rather than the climatic significance of dominantly treeless vegetation.

The juxtaposition of pollen assemblages containing little evidence of local trees with insect assemblages that suggest warm wet conditions similar to today is difficult to reconcile, especially, given the traditional view of the ecological conditions associated with treeless vegetation. In Australia, as in New Zealand, there are several potential explanations. The most likely may relate to the impact of winter climates on trees. Under this scenario, during the last glacial interval trees were not limited by summer temperatures as they are presently, but rather by extreme winter temperatures resulting in lethal frosts that removed trees from all but the most protected landscapes (Harle et al., 2004; McGlone et al., 1993). The western plains of Victoria, for example, with negligible relief and no protection from western- or southerly derived air masses, would be particularly prone to the incursion of polar air masses, resulting in mass death of trees. This explanation reconciles the near total absence of trees in regions with a moderate and moist summer climate that would otherwise seem to be perfectly suitable for the establishment of woodland or forest. Alternatively, as suggested for New Zealand by Marra et al. (2007) and Burge and Schulmeister (2007b), trees may have been more widespread than has been detected in fossil pollen records. In the Australian context, there is little doubt that trees survived *in situ* in pockets of suitable habitat throughout the last glacial interval. Recent molecular evidence demonstrates the extent of *in situ* survival of key forest species in multiple refugia in mainland southeastern Australia and Tasmania (Nevill et al., 2010; Worth et al., 2009, 2010). These sites, incidentally, have long been recognized as key areas of forest refuge because they contain rich and endemic invertebrate taxa (species and some genera). The final explanation is that we may be overinterpreting the climatic significance of our beetle assemblages. Given that similar issues are cropping up in different parts of the globe and using

alternative methodologies, this seems like the least likely explanation. The resolution of this issue will depend on the development of further records, especially LGM records, in order to attempt to reconcile the maintenance of diversity in refugia throughout the late Quaternary, the pollen evidence of massive contraction of forest, and the geomorphic evidence of temperature reduction (Hesse et al., 2004; Williams et al., 2009).

Quaternary Contraction of Wet Forest Biota

It is clear from the southeastern Australian Quaternary beetle record that the range of wet forest biota became increasingly constrained through the Quaternary. The early Pleistocene Stony Creek Basin record demonstrates for both insects and flora that the range of both mesotherm rainforest/wet forest taxa and microtherm cool temperate rainforest/wet sclerophyll taxa (see Sniderman et al., 2009) has been substantially reduced since that time. Although the exact timing of this trend is uncertain, the major part of the contraction almost certainly coincided with the middle Pleistocene transition to drier conditions that is recorded throughout Australia. That this process was continuing in the late Quaternary is demonstrated by the last interglacial Yarra Creek assemblage. This assemblage contains a variety of plant and insect taxa that were living beyond their current range in areas that became too dry for them during the Holocene.

This history of contraction has highly significant implications for understanding the evolution and regional extinction of the Australian biota through the Quaternary. Scientists at the cutting edge of molecular research into the history of biota, whether attempting to reconstruct the relationships of extant taxa or looking at the phylogeography of species, are prone to forget Quaternary history. This history demonstrates that many populations are missing from areas where they once occurred, many species and even genera are regionally or even continentally extinct (better evidenced by the plants but certainly evident in the beetles), and that without Quaternary fossil records we could not begin to reconstruct these histories.

Summary

The development of methods for the reconstruction of past climates in Australia has allowed the exploration of a range of issues that have remained unresolved using traditional approaches like pollen analysis. Foremost is the quantification of past temperature and precipitation values for Quaternary sites ranging from the early Pleistocene to the last glacial, although sites from the latter period, especially the LGM, are still poorly characterized. These quantitative reconstructions provide evidence that in order to more completely understand Quaternary climates and environments, we need an approach that integrates and compares evidence from a range of disciplines, including Quaternary stratigraphy, geochronology, pollen analysis, plant macrofossil analysis, and insect analysis. Further beetle-based research and the development of chironomids as a tool of Quaternary paleoclimatology in Australia (Dimitriadis and Cranston, 2001; Rees and Cwynar, 2010) will enhance our understanding of the nature and limitations of

individual proxies and by so doing enable better understanding of the past climates of the Australian region.

Introduction

In this article, the response of Coleoptera (beetles) to Upper Pleistocene climatic changes are summarized. This should cast light upon our understanding of the nature of these changes and thus enable us to predict the ways in which other animal and plant species might respond to any future climatic events. By using the changes in the range of beetle species during the Quaternary, it has been possible to quantify thermal climatic conditions and to estimate both the amounts and the rates of change involved. Furthermore, it has been possible to map the regional differences in thermal climates within northwestern Europe.

The beetle assemblages described here include those from the Last (Eemian, Ipswichian) Interglacial, the Last (Weichselian, Devensian) Glaciation, and the transition to the present (Holocene) Interglacial. Most of the examples have been drawn from sites in the British Isles and northern Europe because it is there that these faunas have been most intensively investigated. The beetle record shows that the climate oscillated rapidly between temperate–oceanic and arctic–continental conditions. Where possible, the fossil insect assemblages have been correlated with marine isotope stages (MIS) or with the event stratigraphy of the Greenland ice cores. In the account that follows, paleotemperature estimates are given using the mutual climatic range (MCR) method (Atkinson et al., 1987) where $T_{\max}$ indicates the mean temperature of the warmest month (July) and $T_{\min}$ indicates the mean temperature of the coldest months (January and February; [Figure 1](#)).

Upper Pleistocene Beetle Assemblages

Eemian Interglacial (MIS 5e)

Extensive beetle assemblages of this age are known from seven localities in southeast England ([Coope, 2000a](#)). These faunas include a number of southern European species, often occurring in abundance ([Coope, 1990](#)). Quantitative estimates of the thermal climate of these sites have given the following figures: $T_{\max}$ 18–24 °C, $T_{\min}$ –6 to 6 °C. It is likely that the actual mean July temperatures may have been about 21 °C and that mean January/February temperatures may have been about 4 °C. Thus, the mean temperature of the warmest month was of the order of 3 °C warmer than it is in southern England today. Winter figures are more uncertain, but they may not have been much different from those of the present day. Precipitation at that time was sufficient to maintain a vigorous flow in the rivers throughout the year.

The termination of the Eemian Interglacial is difficult to investigate because this stage is apparently missing from all of

the British sequences. However, a borehole at Elsing in the valley of the River Wensum, about 22 km west of Norwich, penetrated Eemian deposits immediately overlain by sediments with arthropod faunas indicative of rapidly alternating climates ranging from temperate to arctic conditions ([Taylor and Coope, 1985](#)).

At the Oerel site, in northwest Germany ([Behre et al., 2005](#)), beetle assemblages were recovered from sediments representing the late part of the Eemian interglacial. They were divided into two different faunal units, in which the older is rather species-rich and indicative of temperate conditions, compared with the younger sparser fauna, which lacked thermophiles. MCR estimates based on the older assemblages are: $T_{\max}$ 14–24 °C, $T_{\min}$ –11 to 6 °C.

Further southwest, at the La Grande Pile site, Vosges, France, beetle remains were analyzed from ten samples assigned to Eemian deposits ([Ponel, 1995](#)). The beetle assemblages were divided into an early and a late faunal unit. The early unit is characterized by an abundance of beetles dependent on deciduous trees, and thermophilous predators and scavengers. MCR estimates based on this assemblage are: $T_{\max}$ 16–22 °C, $T_{\min}$ 0–10 °C. The faunal unit corresponding to the later part of the interglacial includes species feeding on both deciduous and coniferous trees. A number of species indicate a mild and humid climate: $T_{\max}$ 17–26 °C, $T_{\min}$ –6 to 12 °C.

Herning Stadial (MIS 5d)

The insect assemblages from the Oerel and Gross Todtshorn sites in Germany ([Walking, 1997](#)), attributed to this period, are made up of only a few taxa. At Oerel, a few species confined to a marshy environment were identified. At Gross Todtshorn typical heath taxa were recovered. However, the faunas were too small to permit MCR reconstructions to be made. At La Grande Pile one sample included a number of species living on open ground, such as open grassland. However, the MCR estimates do not indicate arctic conditions during this time: $T_{\max}$ 15–19 °C, $T_{\min}$ –15 to 9 °C.

Brørup Interstadial (MIS 5c)

Beetle faunas were described from four sites in central and northern Sweden that were originally thought to be interglacial in age ([Lindroth, 1948](#)) but which are now attributed to an early Weichselian interstadial. These faunas included several exclusively high northern and Asiatic species. More recently, Coleoptera and other insect remains were found and identified from deposits of Brørup age (Peräpohjola) at ten different sites in northernmost Sweden ([Lemdahl, 1997](#)). All the recorded taxa give a very consistent picture of a xeric to mesic tundra environment. A number of the identified species are not found within Fennoscandia today, but in northern Russia and

(1) Early Weichselian sites in northern Sweden, (2) Dimlington, (3) Chelford, (4) Elsing near Norwich, (5) Latton, (6) Cassington near Oxford, (7) South Kensington, (8) Isleworth, (9) Peelo, (10) Oerel, (11) Gross Todtshorn, (12) Belchatów, (13) La Grande Pile, (14) Gossau, (15) full-glacial site near Verona.

Figure 2 (a) The Veiki moraine plateau at Outöjärvi, north easternmost Sweden. Here organic silty sediments dating from the Early Weichselian Brörup interstadial (MIS 5c) were found between 1.5 and 5.5 m below the present soil surface. The sediments are covered by 1.5 m Holocene peat. (b) Sampling of the Early Weichselian sediments for plant macrofossil and insect analyses at Outöjärvi in an open section made by a dredger, during winter time when the upper meter of the ground was frozen.

Mongolia. MCR estimates indicate cold, harsh conditions: $T_{\max}$ 9–11 °C, $T_{\min}$ –20 to –9 °C (**Figure 2(a)** and **2(b)**).

Beetle faunas of this age indicate mixed conifer and birch woodland and are known from several sites in the English Midlands. The most extensively studied is from Chelford, Cheshire (Coope, 1959). MCR analysis of this fauna gives the following figures: $T_{\max}$ 15–18 °C, $T_{\min}$ –11 to 1 °C. It is likely

that the actual figure for $T_{\max}$ was closer to 15°. Thus, the summer temperatures were similar to those in central England today, but the winters were substantially colder.

Results from the Oerel site present two contrasting faunas from this interstadial. The earliest part, of low diversity, included northern species. This was followed by a striking increase in number of species, with terrestrial and aquatic

beetles that today are found only in temperate regions where they inhabit fens and coniferous woodlands. Similar patterns are found in the results from Gross Todtshorn. MCR estimates from Oerel are as follows: $T_{\max}$ 12–19 °C, $T_{\min}$ –21 to 6 °C. At La Grande Pile the assemblage from this time is characterized by a rich fauna of tree-dependent species living on both deciduous and coniferous trees. Climate conditions were likely to have been less temperate than during the Eemian: $T_{\max}$ 13–24 °C, $T_{\min}$ –13 to 10 °C.

Rederstal Stadial (MIS 5b) and Odderade Interstadial (MIS 5a)

Insect assemblages dating to the Odderade Interstadial (Tärendö) were recovered from four Swedish sites (Lem Dahl, 1997). They are characterized by arctic tundra faunas of low diversity. The climatic conditions seem to have been even more severe than those of the Brørup: $T_{\max}$ 10–11 °C, $T_{\min}$ –20 to –17 °C. There are no beetle faunas from Britain that can be unequivocally attributed to MIS 5b and 5a.

The Rederstal assemblages from Oerel and Gross Todtshorn are made up of only a few beetle taxa and indicate the presence of shrub tundra. $T_{\max}$ estimates from Gross Todtshorn are around 11 °C. The Odderade Interstadial is well represented at Oerel where two different insect assemblages reflect two different climate regimes during the period. The first part of the interstadial is characterized by a thermophilous marsh fauna ($T_{\max}$ 13–25 °C, $T_{\min}$ –8 to 10 °C). During the latter part, there is a rather rapid change in which cold stenotherm species replace the temperate fauna ($T_{\max}$ 13–14 °C, $T_{\min}$ –14 to –10 °C). At Gröbern in eastern Germany, the beetle succession showed large scale post-Eemian climatic oscillations that probably belong to this period. These involved changes of at least 7 °C in mean July temperatures (Walking and Coope, 1996). Beetle assemblages dating to the Rederstal from La Grande Pile show a fall in the number of tree-dependent taxa and a cold-adapted species was also recorded ($T_{\max}$ 13–20 °C, $T_{\min}$ –16 to 8 °C). During the Odderade, the number of tree-dependent beetles increased again. The climate was probably slightly cooler than during the Brørup ($T_{\max}$ 12–14 °C, $T_{\min}$ 0–6 °C).

Middle Weichselian Stadials and Interstadials (MIS 4)

This period was climatically complex. There are at least two separate middle Weichselian temperate interstadials in central and southern England separated from one another by a severely cold interval. Both of these temperate episodes postdate MIS 5 (Coope, 2000b) and yielded pollen indicating a treeless landscape. Beetle assemblages are known from three sites in England that date from the earlier of these two interstadials, namely that from Islesworth (Coope and Angus, 1975), the post interglacial deposits at Cassington (Maddy et al., 1998) and from Latton (Lewis et al., 2006). The interstadial beetle assemblages from these sites are rich and diverse and are made up wholly of temperate–oceanic species. Average MCR analyses based on the beetle faunas from these three sites gave the following estimates: $T_{\max}$ 17–18°, $T_{\min}$ –4 to 4 °C.

At Cassington, these temperate interstadial deposits were overlain by gravels in the middle of which organic silts filled a small paleochannel with a fauna made up of an unusual group

of exclusively arctic and continental beetle species. MCR analysis of the beetles from this deposit yielded the following estimates: $T_{\max}$ 7–11 °C, $T_{\min}$ –30 to –10 °C. An almost identical beetle assemblage was also found at South Kensington, London, suggesting that these two deposits are of the same age (Coope et al., 1997). At South Kensington the level containing this arctic fauna was overlain almost immediately by organic silty gravels which yielded a rich interstadial fauna composed entirely of temperate–oceanic beetle species. MCR climatic calculations of this upper temperate interlude gave the following estimates: $T_{\max}$ 16–18 °C, $T_{\min}$ –6 to –1 °C. This temperate period follows so closely on the arctic bed, both of them occurring within the same small channel deposit within the gravel sequence, that it seems likely that the climatic warming took place very rapidly. However, in the absence of reliable dates, the actual rate of climatic change cannot be determined.

It is environmentally significant that, during both these temperate interludes, pollen analysis shows that the landscape in Britain was totally devoid of trees in spite of the climate being warm enough at these times to support mixed oak forest.

Middle Weichselian (MIS 3)

Numerous organic deposits are known from England which have yielded beetle assemblages that can be attributed to the Middle Weichselian on stratigraphical grounds (Coope, 1987a,b), but it is not yet possible to allocate them precisely to their equivalent positions in the Greenland ice-cores chronology.

Several sites that have been radiocarbon dated to about 42.0 ky BP have yielded beetle assemblages that include relatively southern species indicating warmer climates (Coope et al., 1961; Coope 1968, 2000b, 2002). Because of the unreliability of radiocarbon dates of this age, it is not possible at the moment to be sure if these isolated deposits represent just one warm episode; or several of them (i.e., the Upton Warren Interstadial Complex of Coope and Sands (1966)).

A large number of beetle faunas from deposits with radiocarbon dates between 40.0 ky BP and 20.0 ky BP have remarkably consistent assemblages and include numerous species with exclusively arctic and/or Asiatic distributions today (Coope, 1995). Many of these exotic species are represented by large numbers of individuals. MCR estimates have been made on over 20 of these faunas (Coope, 1987b) and an approximate average may be summarized as follows: $T_{\max}$ 9–11 °C, $T_{\min}$ –25 to –10 °C. It is possible that these faunas represent several cold interstadials interspersed with even colder intervals as the Greenland Ice cores suggest (Johnsen et al., 1992) in which case biological activity in Britain may have fallen to a paleontologically invisible minimum.

Although Scotland was totally overridden by ice sheets at the Last Glacial Maximum (LGM), insect-bearing sediments are occasionally found underneath the veneer of glacial deposits. Notable among these is the prolific site at Sourlie, near Irvine, western Scotland, which yielded a rich assortment of plant and animal fossils, including reindeer and woolly rhinoceros as well as abundant insect remains. Radiocarbon dates on plant remains and the collagen from a reindeer antler found *in situ* grouped around 30.0 ky BP (Bos et al., 2004). MCR paleoclimatic estimates based on the beetle fauna gave mean July temperatures of between 6 and 9 °C and mean January/

February temperatures of -34°C and -11°C . A more recent study of a glaciectonized organic deposit at Balglass Burn, high on the slopes of the Campsie Fells east of Glasgow, gave ages between 34.5 and 28.0 ky BP based on six radiocarbon dates on sedge fruits and beetle remains (Brown et al., 2007). Besides insects, pollen and plant macrofossil remains were also studied. All these indicate a small pond situated in an open tundra landscape. MCR estimates based on the beetle assemblage give T_{max} $8-10^{\circ}\text{C}$ and T_{min} -26 to -10°C . The climatic implications of these beetle faunas demonstrate that much of central Scotland was not covered by glaciers during the middle pleniglacial at a time when thermal conditions were apparently sufficiently cold to permit ice accumulation in the highlands. Some other factor such as inadequate precipitation must also have been involved in maintaining ice-free conditions in northern Britain at this time.

In the Netherlands pleniglacial, two extensive Middle Weichselian insect assemblages are known. Thus, a beetle fauna from Peelo included many of the exclusively arctic and/or Asiatic species that were also present in the British Isles at the same time (Coope, 1969). Excavations at Orvelte, near Drenthe, to recover mammoth and woolly rhinoceros remains, enabled a large beetle fauna to be investigated that included an assemblage of cold-adapted species similar to the ones discussed above (Cappers et al., 1993). Both of these faunas yield MCR T_{max} temperature estimates at or below 10°C and T_{min} values below -20°C .

A Middle Weichselian insect fauna from Poland included a very similar group of high arctic and Asiatic species (Kasse et al., 1998). MCR estimations based on this assemblage gave the following estimates: T_{max} $8-12^{\circ}\text{C}$, T_{min} -27 to -20°C .

Insect remains were found in deposits referring to the Oerel interstadial both at the Oerel site and at Gross Todtshorn. The beetle assemblages are composed of northern Palaearctic species, which indicate a treeless environment and cold climate (T_{max} $12-13^{\circ}\text{C}$, T_{min} -9 to -2°C). At the Oerel site, insect remains were also recovered from a peat layer referred to the younger Glinde Interstadial. The beetle assemblage from this horizon is similar in composition to those from the earlier interstadial. Climate conditions were also likely to have been very similar (T_{max} $9-14^{\circ}$, T_{min} -17 to -2°C).

In Switzerland, two insect assemblages of middle Weichselian age have been recorded from Gossau (Jost-Stauffer et al., 2005). They include several exclusively arctic and Asiatic species that do not occur anywhere in central Europe at the present day. MCR estimates gave the following figures: T_{max} $8-13^{\circ}\text{C}$, T_{min} -21 to -7°C . A second beetle assemblage from the Swiss plateau was obtained from samples taken in a peaty matrix of the mammoth skeleton at Niederweningen that was radiocarbon dated to around 45.0 ky BP (Coope, 2007). This fauna also includes many exclusively arctic/Asiatic species. The mammoths were probably mired in a reedy swamp in a landscape with scattered willows, birches, and conifers. An MCR estimate indicates T_{max} around 10°C and T_{min} below -10°C .

Middle Weichselian beetle assemblages from La Grande Pile are characterized by the presence of almost entirely arctic and continental species. Obligate tree-dependent species were not recorded. The climate was cold in general through the period (T_{max} around 12°C , T_{min} approximately -10°C or below).

A site of outstanding archaeological importance has recently been recorded at Lynford, Norfolk, where an extensive

beetle fauna was found in close association with abundant evidence of Neanderthal exploitation of mammoths: smashed bones and numerous flint tools (Boismier et al., 2011). There can be little doubt that the beetle assemblage is contemporary with the human activities and provides an intimate view of the local environment (Coope, 2011). However, the beetle assemblage was unusual. It included abundant high northern and Asiatic species suggesting cold continental climatic conditions. But this fauna lacks several of the extreme cold-adapted species present in the typical full-glacial assemblages and includes rare species whose distributions do not extend into arctic regions today. These make MCR estimates difficult. Nevertheless, it is likely that the mean July temperatures were between 12 and 14°C and January/February figures at or below -10°C . The age of this important site is probably sometime late in MIS 4 or early MIS 3.

Last Glacial Maximum (MIS 2)

Conditions during the LGM were extremely harsh and insect faunas from this period are consequently very rare. A small beetle assemblage obtained from Dimlington, East Yorkshire, has been radiocarbon dated to 18.5 ky BP (Penny et al., 1969). Given the smallness of this insect fauna, only a provisional MCR estimate is possible: T_{max} $9-11^{\circ}\text{C}$, T_{min} -27 to -7°C . These figures do not necessarily represent the typical climate at the LGM for England because the insects came from a single fossiliferous horizon in an otherwise barren sequence of laminated silts and may thus indicate a short period of atypically warm conditions in an otherwise even colder episode.

In continental Europe, two beetle assemblages are known from the LGM. Beetle assemblages from La Grande Pile dating to this period indicate very cold and harsh conditions, with T_{max} mostly around 10°C and T_{min} well below -10°C . Fossil remains of beetles and oribatid mites, which are dated to around 18 800 BP, were recovered from a site close to Verona, northeastern Italy (Foddai and Minelli, 1994). They indicate climate conditions colder and wetter than today. T_{max} may have been $8-9^{\circ}\text{C}$ lower than present day.

Late Glacial Period

This period falls well within the radiocarbon dating techniques. Dates are cited here in radiocarbon years BP and calibrated calendar years are shown in parentheses as cal years BP. Correlations are made with the climatic event stratigraphy of the Greenland Ice cores (Walker et al., 1999). As a large number of studies have been carried out on beetle assemblages from sites scattered all over Europe (cf. Coope et al., 1998), only a representative selection is discussed here (Figure 3).

Late Glacial stadial (Greenland stadial 2)

Faunas that date from the cold period (Greenland stadial 2, GS-2) that immediately preceded the Late Glacial Interstadial, namely from just before 13.0 ky BP (ca. 15.4 cal ky BP), are rare. In Britain, the most stratigraphically secure faunal assemblage of this age is from the North Wales coast at Glanllynau, where a sequence of insect-bearing deposits spans almost the whole of the early part of the Late Glacial Interstadial (Coope and Brophy, 1972, cited in Coope et al., 1998). The stadial

Late Glacial sites

Figure 3 Map showing Late Glacial sites where fossil beetle assemblages were studied.

deposits yielded exclusively arctic and Siberian species. MCR calculations on this assemblage gave the following estimates: $T_{\max}$ 10–11 °C, $T_{\min}$ –26 to –23 °C.

A second beetle assemblage of this age was associated with the recovery of the skeletons of an adult mammoth plus at least three juveniles from silty clay in a kettle hole at Condover, near Shrewsbury (Allen et al., 2009). The GS-2 stadial beetle fauna included many exclusively high arctic species, but unfortunately the wallowing of the mammoths in their efforts to extricate themselves from the adhesive clay had churned up the sediment, incorporating some of the more recent Late Glacial sediment into the stadial deposits, making the precise interpretation of the environment difficult. It is, however, clear that the stadial assemblage of beetles lacked the eastern Asiatic component so characteristic of the full-glacial faunas, suggesting that although the climate must have been of arctic severity at this time, it was probably less continental than during the mid-glacial (pleniglacial) episode.

Only two beetle assemblages of this age are known from northern Europe. Both of these faunas are from Kullaberg, southwestern Sweden, and can be dated with confidence to this period (Lemdahl, 1988, cited in Coope et al., 1998). Although these include only a few species, they resemble those from Britain. Similarly, cold-adapted suites of beetle species are also known from Poland, and from the Swiss Plateau (Coope and Elias, 2000; Coope and Lemdahl, 2009; Elias and Wilkinson, 1983; Gaillard and Lemdahl, 1994; Hardon et al., 2000). MCR estimates gave the following figures: $T_{\max}$ 10–13 °C, $T_{\min}$ –17 to 0 °C.

Late Glacial interstadial

Beetle faunas from the Late Glacial interstadial 1 (GI-1) are widespread across the whole of northwestern Europe. In Britain, important faunas have been described from Glanllynau, North

Wales (Coope and Brophy, 1972, cited in Coope et al., 1998), St Bees, Cumbria (Coope and Joachim, 1980, cited in Coope et al., 1998), Gransmoor, East Yorkshire (Walker et al., 1993, cited in Coope et al., 1998), Hollywell Coombe, Kent (Coope, 1998) and from Llanilid, South Wales (Walker et al., 2003).

Faunas from the early part of the GI-1e interstadial (the Bølling phase) from about 12.8 ky BP (15.1 cal ky BP) or slightly earlier, include an ecologically diverse variety of relatively southern species. At this time the vegetation was thin and made up chiefly of pioneer plant species. The only trees that were present were birches and willows and these were probably confined to the damp valley bottoms. At this time northern Europe as a whole was largely without a woodland cover in spite of the fact that for much of the region, the climate was warm enough to have supported mixed oak forest. Edaphic factors are thought to have been largely responsible for this open landscape. Average MCR estimates from these sites give approximate figures: $T_{\max}$ 17–18 °C, $T_{\min}$ –7 to –1 °C.

Beetle faunas indicate that the initial warming at the start of the interstadial involved a rapid rise in mean July temperatures of at least 7 °C and a corresponding rise in winter temperatures substantially greater than this. The rate at which the mean July temperature rose was about 1 °C per decade and even higher (Coope and Brophy, 1972, cited in Coope et al., 1998). Because this change also involved a switch from continental to oceanic climatic conditions, the rise in *mean annual* temperature was considerably greater than these figures suggest, though the precise number of degrees involved is impossible to estimate with confidence. The beetle reconstruction that yielded this unexpectedly high rate of climatic change has subsequently been supported by evidence from the Greenland Ice cores, which show a dramatic climatic amelioration at about this time (Johnsen et al., 1992).

It is interesting to observe that this episode of rapid climate warming at the start of the Late Glacial Interstadial is not recorded by beetle assemblages from southern Sweden (Lemdahl, 1988, cited in Coope et al., 1998) or from the coast of western Norway. During this period, the Scandinavian beetle assemblages are of an arctic or boreal character. It is likely that this reflects the local cooling effect provided by the close proximity of the waning Fennoscandian ice sheet.

In contrast to the Scandinavian situation, faunas from Poland and the Netherlands (Geel et al., 1989, cited in Coope et al., 1998) indicate temperatures similar to those of the British Isles. At about the same time, warmth demanding beetle faunas are recorded from the Swiss Plateau (Coope and Elias, 2000; Coope and Lemdahl, 2009; Elias and Wilkinson, 1983; Gaillard and Lemdahl, 1994; Hardon et al., 2000). Similar faunal changes are traced in southern France (Ponel and Coope, 1990; Ponel et al., 2001).

Shortly before 12.0 ky BP (ca. 14.0 cal ky BP), there was a sudden climatic cooling. $T_{\max}$ figures suddenly fell to around 15 °C or even lower and never recovered again during the rest of the interstadial; in other words for much of Western Europe the whole of the Allerød phase was substantially cooler than the preceding Bølling phase. The beetles indicate that during the Allerød there appears to have been several relatively minor climatic oscillations, well illustrated by the climatic curves from Gransmoor (Walker et al., 1993, cited in Coope et al., 1998) and Llanilid (Walker et al., 2003, and in summary by

Figure 4 Fieldwork at the small marsh ($\sim 80 \times 30$ m) at Hérémence situated at 2290 m.a.s.l. in the Swiss Alps. Four sites at different altitudes, including this site, were studied in a multiproxy project in order to record biotic responses to rapid climatic changes around the Younger Dryas in the Swiss Alps. Samples were recovered by using a Streif-piston corer of 8 cm diameter.

Lowe and Walker, 1997, cited in Coope et al., 1998). The frequency of these oscillations makes it difficult to give useful MCR estimates for the latter half of the Late Glacial Interstadial.

Again, in contrast to the British Isles and much of Europe, the beetle assemblages from southern Sweden indicate that the highest temperatures were reached during the latter part of the Late Glacial Interstadial. However, it must be emphasized that the actual MCR temperature estimates were similar to the British figures at this time. In Norway arctic faunas are recorded for the Allerød phase (Birks et al., 1993, cited in Coope et al., 1998; Lemdahl, 2000a). In Poland species with a boreal distribution appear during this period (Lemdahl, 1991a, cited in Coope et al., 1998), which also seems to be the case in southern France. These beetle assemblages show that during the GI-1 there were distinct regional differences in climate and steep temperature gradients across much of northern Europe (Coope and Lemdahl, 1995; Coope et al., 1998).

Late Glacial stadial (GS-1) = Younger Dryas

The beetle evidence from the British Isles suggests that the beginning of the GS-1 (Younger Dryas) cold period appears as a culmination of the sequence of Allerød cooling events outlined above. Its beginning is conveniently dated at about 11.0 ky BP (ca. 13.0 cal ky BP). Many beetle assemblages are known from the Younger Dryas period (e.g., Coope et al., 1979, Coope and Joachim, 1980, cited in Coope et al., 1998; Coope, 1998; Walker et al., 1993, 2003) and include a large number of exclusively arctic species, many of which were previously encountered in the assemblages from full-glacial times. However, exclusively Asiatic species are very rare at this time. An average of MCR estimates based on faunas from this period indicates the following figures: $T_{\max}$ 9–11 °C, $T_{\min}$ –10 to –20 °C (Figures 4 and 5).

In northern France, insect assemblages from Younger Dryas fluvial deposits recorded at St.-Momelin, yielded these MCR estimates: $T_{\max}$ around 10 °C and $T_{\min}$ close to –12 °C (Poné

Figure 5 Fossil head and thorax matching a modern specimen of the carrion beetle *Thanatophilus dispar*. Remains of this species were abundant in lake sediments dating to the Oldest Dryas (GS-2) at the site Hauterive Rouges-Terres, at the shore of the Lake Neuchâtel, Switzerland. A Paleolithic settlement was excavated adjacent to the site. Today *T. dispar* is mainly found on fish carrion where it probably feeds on fly larvae.

et al., 2007). MCR reconstructions show that, in contrast to the Late Glacial Interstadial, relatively similar climatic conditions seem to have prevailed in most of northern Europe at this time. In eastern Finland high arctic beetle faunas of Younger Dryas and early post glacial age colonized recently deglaciated areas (Bondestam et al., 1994). Although Younger Dryas beetle assemblages are very rare from the Swiss Plateau, they suggest cold, arctic conditions (Lemdahl, 2000b).

Many sites that include the transition from the Late Glacial to the Holocene show signs of a hiatus, making it difficult to estimate the rate of change involved. However, all the available beetle evidence suggests that the change was abrupt and intense and probably similar in magnitude to the one at the start of the Late Glacial Interstadial (e.g., Ashworth, 1973; Lemdahl, 1991b, cited in Coope et al., 1998; Lemdahl, 2000; Poné et al., 2007). The beetles indicate that throughout most of Europe at the start of the Holocene, temperatures reached present day levels in a geologically immeasurably short period of time.

Introduction

The study of Japanese Quaternary insects began in 1978 at the Tategahana Site of the Nojiri-ko Site Group, Nagano Prefecture. This study was carried out by the Fossil Insect Research Group for Nojiri-ko Excavation (FIRGNE). Tategahana is a Paleolithic site, yielding bone artifacts and large-mammal fossils, formed on the shore of Lake Nojiri (Japanese name, Nojiri-ko) during the last glaciation. In total, the research group has so far identified 85 species of beetles from the site (see discussion of the Nojiri-ko insect fauna, below). This research group also studied the methodology of Quaternary Entomology and published a Japanese handbook on fossil insects (FIRGNE, 1988).

In Japan, Quaternary peat beds have yielded abundant fossil beetles, especially ground beetles (Carabidae) and donaciine leaf beetles (Donaciinae). Last glacial peat beds are known from many Japanese regions but only a few studies on fossil beetles have so far been performed. However, Japanese Quaternary entomologists have recorded 115 species of beetles from 16 sites (Tables 1, 2). These beetle records are reviewed here.

Fossil Sites

Sixteen fossil sites are shown in Table 1 and Figure 1. Most sites are on Honshu, the main island of Japan, and only one site is on Kyushu, in western Japan (Figure 1). The late Pleistocene fossil beds are mainly discovered in archaeological excavations, terrace deposits, and lake deposits.

The Owatari II Site is on the lower terrace of Waga River, Yuda-machi, Iwate Prefecture. The terrace deposit is intercalated with three peat beds, identified as the “1st” peat (ca. 14–12 ka), the “2nd” peat (ca. 23–19 ka), and the “3rd” peat (ca. 25–24 ka), respectively (Mori, 1995). Twenty-eight taxa of beetles from these deposits have been recorded by Mori (1995). These include *Elaphrus japonicus* (Carabidae), *Ilybius poppiusi* (Dytiscidae), *Dineutus orientalis* (Gyrinidae), *Enochrus* sp. (Hydrophilidae), *Plesiophthalmus* sp. (Tenebrionidae), and *Plateumaris sericea* (Chrysomelidae). Mori recognized two unidentified species of the genus *Agabus* (Dytiscidae) as being extinct species in Japan.

The Tomizawa Site is on Sendai Plain, Sendai City, Miyagi Prefecture. Late Pleistocene beetles were found from the ‘27th’ to ‘25th’ beds of the site. Mori and Itoh (1992) recorded 43 taxa of beetles from the beds, such as *Pterostichus* sp. (Carabidae), *Noterus japonicus* (Noteridae), *Ilybius poppiusi* (Dytiscidae), *Laccobius bedeli* (Hydrophilidae), *Geotrupes auratus* (Scarabaeidae), *Donacia splendens* (Chrysomelidae), and *Limnobaris* sp. (Curculionidae).

The Maebashi Peat Formation (Figure 2) is found in the Maebashi Terrace, Takasaki City and Maebashi City, Gunma

Prefecture. The formation is characterized by peat beds intercalated with silt, sand, gravel beds, and volcanic ash layers. Hayashi (1996, 2005) reported fossil beetles from peat beds at two sites, Sojya in Maebashi City and Shimowada in Takasaki City. The base of the peat at the Shimowada site is older than that of the Sojya site. The age of the Shimowada peat is ca. 2.0 ka (Nirei and Hayashi, 2004). Hayashi (1996) recorded 10 taxa from the Sojya Site and Hayashi (2005) recorded 14 taxa from the Shimowada Site.

The Tsukumogawa Peat Bed is in the lower terrace deposit of the Tsukumogawa River, Annaka City, Gunma Prefecture. The Aira-Tn tephra, dated ca. 25–24 ka, overlies the peat bed. Hayashi and Shimadu (2005) recorded 12 taxa of beetles from the bed, such as *Chlaenius* sp. (Carabidae), *Agabus* sp. *Ilybius* sp., *Hydrochara libera* (Hydrophilidae), and *Donacia splendens*.

The Nukui Peat Bed is found in Nukui, Agastuma-machi, Gunma Prefecture. The peat bed is intercalated with the Aira-Tn tephra. *Damaster blaptoides* (Carabidae) and *Plateumaris* sp. (Chrysomelidae) were found in this bed.

The Taguro Peat Bed is distributed in Taguro, Tamagawamura, Saitama Prefecture. A radiocarbon date from the wood was more than 38 020 yr BP (Gak-19303). Nirei and Hayashi (1998) recorded six taxa of beetles from this deposit: *Elaphrus japonicus*, *Tachyura* sp., *Agabus conspicuus*, *Plateumaris constricticollis*, *Plateumaris sericea*, and *Donacia splendens*.

The Nojiri-ko Site Group in Shinano-machi, Nagano Prefecture includes Tategahana, Nakamachi, Ikejirigawa, and other sites (Figure 3). Fossil beetles were found from three of the sites. The Upper Pleistocene in the site groups is divided into three strata: the Biwajima-oki Peat Formation (ca. 100–70 ka), the Kannoki Formation (ca. 60 ka) and the Nojiri-ko Formation (ca. 50–10 ka), respectively. The Nojiri-ko Excavation Research Group has excavated the Nojiri-ko Formation from these three sites. The Biwajima-oki Peat Formation and the Kannoki Formation have been excavated at the Nakamachi Site. The last glacial beetles from the group of sites have been reported by FIRGNE (1980, 1984, 1987, 1990, 1993a,b, 1996a,b, 2000a,b, 2003).

The Ono Peat bed is located in Ono, Tatsuno-machi, Nagano Prefecture. Its age is ca. 60 ka. Hayashi (1998) recorded eight species of beetles from the bed, including well-preserved fossils of *Agabus japonicus* (Dytiscidae) and *Plateumaris sericea*.

The Miomote Site Group is on river terraces of the Miomote River, Asahi-mura Niigata Prefecture. This group includes Tarukuchi (Figure 4), Garahagi, and other sites. Two peat beds were found from the Tarukuchi Site. The upper peat bed overlies the Aira-Tn tephra. These peat beds yielded *Carabus vanvolxemi* (Carabidae), *Agabus miyamotoi* (Dytiscidae), *Silpha longicornis* (Silphidae), *Plateumaris sericea* and some undetermined beetles (Hayashi and Miyatake, 1996). A radiocarbon age from the peat bed of the Garahagi Site was more than

35 900 yr BP (Gak-18168). Hayashi and Miyatake (1996) recorded nine taxa of beetles from the bed, including *Elaphrus japonicus*, *Agabus* sp., *Coelostoma orbiculare*, *Donacia splendens*, and *Plateumaris constricticollis*.

The Yasuda Formation is a deposit from the last interglacial (MIS 5e) in Kashiwazaki City, Niigata Prefecture. Abundant fossil beetles comprising 24 taxa were obtained from the formation during the excavation of the Naumann's Elephant

Figure 1 Late Pleistocene fossil sites in Japan. Site numbers match those in Table 1.

Figure 2 The Maebashi Peat Formation in Shimowada, Takasaki City, Gunma Pref. © 2005, Photograph, M. Hayashi.

(*Palaeoloxodon naumanni*) in 1986 (Kashiwazaki Naumann's Elephant Research Group, 1991). Beetle faunas from the last interglacial are poorly studied in Japan. The fauna is dominated by water beetles, ground beetles, plant-feeding beetles, and dung beetles. Most species are still found today at the fossil site and in the surrounding regions, but a dung beetle, *Copris tripartitus* is no longer living on the island of Honshu. The ground beetles include *Carabus insulicola*, *Scarites terricola pacificus*, *Lesticus magnus*, *Pterostichus planicollis*, *Epomis nigricans* and *Chlaenius circumdatus*. The plant-feeding beetles include four donaciine beetles of *Donacia ozensis*, *Donacia lenzi*, *Donacia provostii* and *Donacia vulgaris*. The paleoenvironments of the Yasuda Formation have been reconstructed as ranging from

forest edges to grassland, surrounding an area of still water with emergent and floating vegetation.

The Miyanomae Site is on a terrace of the Miyagawa River, Miyagawa-mura, Gifu Prefecture. Twenty-four taxa of beetles were found from the late Paleolithic horizon, radiocarbon dated between 14–12 ka (Mori et al., 1997).

The Mizozono Formation (Figure 5) is a late Pleistocene deposit in Yoshimatsu-cho, Kagoshima Prefecture, but its exact age is unknown. Hayashi et al. (2002) recorded 36 taxa of beetles, such as *Hister simplicisternus* (Histeridae), *Eusilpha japonica* (Silphidae), and *Onthophagus lenzii* (Scarabaeidae), and *Donacia flemora* (Chrysomelidae) from this site.

Fossil Records

The fossil beetles identified from the various Upper Pleistocene fossil assemblages in Japan are shown in Table 2.

Carabidae

Abundant ground beetle fossils are typically found in Japanese peat beds, but their specific identification has been difficult for Japanese Quaternary entomologists. Therefore, most fossils have been identified only to the subfamily or tribe level. Twenty-one species are recorded from ten sites (Table 2): six species of Carabinae, one species of Elaphrinae, one species of Scaritidae, eight species of Pterostichinae, four species of Callistinae, and one species of Lebiinae. *Elaphrus japonicus* (Figure 6) is recorded from five sites and *Carabus granulatus* (Figure 7) is recorded from four sites. Today these species inhabit marshes.

Dytiscidae

Thirteen species of predaceous diving beetles are recorded from eleven Japanese sites (Table 2). These comprise nine species of Colymbetinae and four species of Dytiscinae. *Agabus japonicus* (Figure 8) and *Ilybius poppiusi* (Figure 9) are each known from three sites. Two species of *Dytiscus* are recorded from the Nojiri-ko Site Group: *D. marginalis czerskii* (Figure 10) from the Nojiri-ko Formation in the Tategahana, and *D. sharpi* (Figure 11) from the Kannoki Formation in the Nakamachi Site.

Hydrophilidae

Ten species of water scavenger beetles have been recorded from ten sites (Table 2): three species of Sphaeridiinae, two species of Hydrobiinae, four species of Hydrophilinae, and one species of Chaetritrinae. *Coelostoma orbiculare* (Figure 12) is known from nine sites and *Hydrochara libera* is known from six sites. Most of these beetles are aquatic species but *Pachysternum haemorrhoum* is a dung-feeder.

Gyrinidae

One species of whirligig beetle, *Dineutus orientalis*, is recorded from the Owatari II, Ikejirigawa, and Tategahana Sites. Undetermined specimens of *Gyrinus* spp. are known from several sites.

Figure 4 (a), The Tarukuchi Site in Asahi-mura, Niigata Pref.; (b), peat bed in the site. © 2005, Photograph, M. Hayashi.

Histeridae

Four species of hister beetles are recorded from three sites (Table 2): *Atholus duodecimstriatus* (Figure 13) and

Figure 5 The Mizozono Formation in Shimogose, Yoshimatsu-cho, Kagoshima Pref. © 2005, Photograph, E. Kitabayashi.

Margarinotus niponicus from the Nakamachi Site, *Hister concolor* (Figure 14) from the Tategahana Site, and *Hister simplicisternus* from Shimogose, Kagoshima Prefecture.

Silphidae

Five species of carrion beetles are recorded from five sites: one species of Nicrophorini and four species of Silphini. *Silpha longicornis* (Figure 15) is known from three sites. This species is currently found in the cool-temperate zone forests in Japan.

Staphylinidae

Indetermined fossils of the rove beetle family are commonly found from the Pleistocene peat beds but one species, *Paederus parallelus* is recorded from the Tategahana Site.

Scaphidiidae

Fossils of this family (shining fungus beetles) are poorly known in Japan. One species, *Scaphidium rufopygum* (Figure 16) is recorded from the Tategahana Site.

Figure 6 *Elaphrus japonicus*, mesosternum and right elytron, from the Nojiri-ko Formation in the Ikejirigawa Site. © 2005, Photograph, FIRGNE. Scale bar = 1 mm.

Figure 7 *Carabus granulatus*, left elytron, from the Nojiri-ko Formation in the Tategahana Site. © 2005, Photograph, FIRGNE. Scale bar = 1 mm.

Lucanidae

Two species of stag beetles are recorded (Table 2): *Nipponodorcus rubrofemoratus* from the Tategahana Site and *Platycerus acuticollis* (Figure 17) from the Ikejirigawa Site. *P. acuticollis* currently lives in the cool-temperate zone forest in Japan.

Figure 8 *Agabus japonicus*, elytra and sternum, from the Ono Peat Bed. © 2005, Photograph, M. Hayashi. Scale bar = 1 mm.

Figure 9 *Ilybius poppiusi*, left elytron, from the Maebashi Peat Formation. © 2005, Photograph, M Hayashi. Scale bar = 1 mm.

Geotrupidae

One species of earth-boring dung beetle, *Geotrupes auratus* (Figure 18), is recorded from four sites. It is found today in broad-leaved forests of mountain regions, where it feeds on animal dung.

Scarabaeidae

Twenty-one scarab beetle species are recorded from seven sites (Table 2): five species of Scarabaeinae, eight species of Aphodiinae, five species of Rutelinae, three species of Cetoniinae.

Figure 10 *Dytiscus marginalis czerskii*, right elytron, from the Nojiri-ko Formation in the Tategahana Site. © 2005, Photograph, FIRGNE. Scale bar = 1 mm.

Figure 11 *Dytiscus sharpi*, head, from the Kannoki Formation in the Nakamachi Site. © 2005, Photograph, FIRGNE. Scale bar = 1 mm.

Thirteen species of Scarabaeinae and Aphodiinae are dung-feeders and the other species of subfamilies are plant-feeders.

Byrrhidae

One species of pill beetle, *Cytilus sericeus* (Figure 19), is recorded from the Nakamachi Site and Ono, Nagano Prefecture.

Elateridae

Undetermined fossils of click beetles are commonly found from the Pleistocene peat beds. One species, *Selatosomus puncticollis* is recorded from the Nakamachi Site.

Figure 12 *Coelostoma orbiculare*, left elytron, from the Nojiri-ko Formation in the Ikejirigawa Site. © 2005, Photograph, FIRGNE. Scale bar = 1 mm.

Figure 13 *Atholus duodecimstriatus*, right elytron, from the Biwajima-oki Peat Formation the Nakamachi Site. © 2005, Photograph, FIRGNE. Scale bar = 1 mm.

Lagriidae

Fossils of the long-jointed beetle family are poorly known in Japan. One species, *Luprops cribrifrons* is recorded from the Miyanomae Site.

Trogossitidae

Fossils of the bark-gnawing beetle family are poorly known in Japan. One species, *Leperina squamulosa* (Figure 20) is recorded from the Tategahana Site.

Figure 14 *Hister concolor*, right elytron, from the Nojiri-ko Formation in the Tategahana Site. © 2005, Photograph, FIRGNE. Scale bar = 1 mm.

Figure 17 *Platycerus acuticollis*, pronotum, from the Nojiri-ko Formation in the Ikejirigawa Site. © 2005, Photograph, FIRGNE. Scale bar = 1 mm.

Coccinellidae

Fossils of the ladybird family are poorly known in Japan. One species, *Harmonia axyridis* is recorded from the Tategahana Site.

Cerambycidae

Two species of long-horn beetles are recorded, *Pterolophia caudata* (Figure 21) from the Tategahana Site and *Spondylis buprestoides* from the Miyanomae Site.

Chrysomelidae

Twenty-one species of leaf beetles are recorded from fifteen sites (Table 2): eleven species of Donaciinae, one species of Eumolpinae, six species of Chrysomelinae, and three species of Galerucinae. *Plateumaris constricticollis* (Figure 22) is known from nine sites and *Donacia splendens* (Figure 23) is known from seven sites. These two species of Donaciinae are commonly found from the Pleistocene peat beds in Japan.

Figure 21 *Pterolophia caudata*, right elytron, from the Nojiri-ko Formation in the Tategahana Site. © 2005, Photograph, FIRGNE. Scale bar = 1 mm.

Attelabidae

Three species of leaf-rolling beetles are recorded from two sites (Table 2): *Byctiscus puberulus* from the Owatari II Site and the Tategahana Site, *Byctiscus venustus* and *Euops punctatostriatus* from the Tategahana Site.

Curculionidae

Four weevil species are recorded from five sites (Table 2): one species of Baridinae and three species of Hylobiinae. *Limnobaris japonica* (Figure 24) is known from two sites that lives in marsh and eats leaves of *Carex* spp.

Figure 22 *Plateumaris constricticollis*, pronotum, from the Nojiri-ko Formation in the Ikejirigawa Site. © 2005, Photograph, FIRGNE. Scale bar = 1 mm.

Nojiri-Ko Insect Fauna

The Nojiri-ko insect fauna comprises the last glacial insects from the Nojiri-ko Site Group, including 85 species of beetles from the Nojiri-ko, the Kannoki, and the Biwajima-oki Peat Formations. The fauna is dominated by water beetles, ground beetles, plant-feeding beetles, and dung beetles. Most species are found today in the cool-temperate zone of Japan.

The aquatic beetles include Dytiscidae, Hydrophilidae and Gyrinidae. Species of *Agabus*, *Ilybius*, *Rhantus*, *Dytiscus*, *Cybister*

Figure 25 *Cybister brevis*, head, from the Biwajima-oki Peat Formation in the Nakamachi Site. © 2005, Photograph, FIRGNE. Scale bar = 1 mm.

Figure 26 *Hydrophilus acuminatus*, head, from the Nojiri-ko Formation in the Tategahana Site. © 2005, Photograph, FIRGNE. Scale bar = 1 mm.

Figure 27 *Platambus pictipennis*, left elytron, from the Nojiri-ko Formation in the Tategahana Site. © 2005, Photograph, FIRGNE. Scale bar = 1 mm.

Figure 28 *Pterostichus prolongatus*, pronotum, from the Biwajima-oki Peat Formation in the Nakamachi Site. © 2005, Photograph, FIRGNE. Scale bar = 1 mm.

(Figure 25), *Coelostoma*, *Anacaena*, *Enochrus*, *Hydrophilus* (Figure 26), *Sternolophus*, *Hydrochara*, *Regimbartia*, and *Dineutus* live in areas of still water with emergent and floating vegetation. *Platambus pictipennis* (Figure 27) lives in streams. This species is found in the Nojiri-ko Formation at the Tategahana Site.

The terrestrial beetles include Carabidae, Histeridae and Silphidae. Most of them live on the forest floor and/or its edge. Five species live in wet ground with vegetation, including *Carabus granulatus* (Figure 7), *Elaphrus japonicus* (Figure 6), *Pterostichus prolongatus* (Figure 28), *Epomis nigricans*, and *Chlaenius gebleri* (Figure 29). Two species, *Calosoma inquisitor* (Figure 30) and *Calleida lepida* live in trees, not on the ground.

Figure 29 *Chlaenius gebleri*, pronotum, from the Biwajima-oki Peat Formation in the Nakamachi Site. © 2005, Photograph, FIRGNE. Scale bar = 1 mm.

Figure 30 *Calosoma inquisitor*, elytron, from the Nojiri-ko Formation in the Tategahana Site. © 2005, Photograph, FIRGNE. Scale bar = 1 mm.

The plant-feeding beetles include Lucanidae, Scarabaeidae (the genera *Mimela*, *Anomala*, *Rhomborrhina* and *Eucetonia*), Cerambycidae, Chrysomelidae, Attelabidae and Curculionidae. Most of these species live in forests and/or the forest edge. Species of *Plateumaris*, *Donacia*, and *Limnobaris* are tied to aquatic host-plants, such as Cyperaceae, Potamogetonaceae, Sparganiaceae, Typhaceae, and Nymphaeaceae.

The dung-feeding beetles include *Pachysternum haemorrhoum* (Figure 31) (Hydrophilidae) and dung beetles (Scarabaeidae) in the genera *Copris* (Figure 32), *Caccobius*, *Onthophagus* and *Aphodius* (Figure 33). Two extinct mammals,

Figure 31 *Pachysternum haemorrhoum*, left elytron, from the Nojiri-ko Formation in the Tategahana Site. © 2005, Photograph, FIRGNE. Scale bar = 1 mm.

Figure 33 *Aphodius brachysomus*, left elytron, from the Nojiri-ko Formation in the Tategahana Site. © 2005, Photograph, FIRGNE. Scale bar = 1 mm.

Figure 32 *Copris pecuarius*, pronotum, from the Nojiri-ko Formation in the Tategahana Site. © 2005, Photograph, FIRGNE. Scale bar = 1 mm.

Naumann's elephant (*Palaeoloxodon naumanni*) and Yabe's giant fallow deer (*Sinomegaceros yabei*) have been excavated from the Nojiri-ko Formation in the Tategahana Site. The dung beetles from the Tategahana Site may have fed on the dung of these mammals.

Biogeography

The Japanese Islands are surrounded by sea, therefore one might expect many endemic species to be found on the islands. However, during the Pleistocene, these islands were connected

to continental Asia during intervals of lowered sea level. Modern entomologists have speculated that many recent species immigrated to the Japanese Islands during the last glaciation (e.g. Ishikawa, 1988). However, late Pleistocene fossil records indicate that the recent fauna was formed before the last glaciation.

Distributional ranges of beetles have shifted in response to environmental changes in geologic time. The transition from glacial to interglacial intervals exerted a particularly strong influence on these shifts. For example, *Copris tripartitus*, recorded from the Yasuda Formation in Niigata Prefecture, is found today on Tsushima Island, Chejido Island, Korea, and China. The fossil record indicates that *C. tripartitus* lived on Honshu during the last interglaciation, and died out there during the last glacial age. On the other hand, two dytiscid beetles, *Ilybius poppiusi* (Figure 9) and *Ilybius weymarni* (Figure 34), were recorded from several fossil assemblages from the last glaciation on eastern Honshu. These are currently found on Hokkaido and in northern Asia. The fossil records indicate that they had been living on Honshu during the last glaciation and died out there during the Holocene. *Cytilus sericeus* (Figure 19) was also recorded from several last glacial deposits on eastern Honshu. It is found today on Hokkaido and across Asia to Europe. The distribution of these species may have been influenced by the climatic change of the Pleistocene-Holocene transition.

Future of Japanese Quaternary Entomology

Japanese Quaternary entomology will continue to supply vital information on the evolution of Japanese beetle fauna. The

Figure 34 *Ilybius weymarni*, left elytron, from the Maebashi Peat Bed. © 2005, Photograph, M. Hayashi. Scale bar = 1 mm.

framework of speciation in the islands differs from that in continental regions. The formation of land bridges between island and continent or island and island are the most important element of the regional zoogeography. In the island arcs, the formation of land-bridges was caused by a combination of lowered sea level and/or uplifting of the sea floor. Japanese evolutionary scientists try to reconstruct biogeographic histories based on molecular phylogenetic trees and paleogeographic maps. However, they lack useable timescales for their theories, because the land bridge was repeatedly formed during geologic time. The fossil beetle record from Quaternary deposits provides concrete evidence that species were living at the fossil locality in times past. Therefore, evolutionary scientists are seeking information from Quaternary entomologists about the fossil records. To date, the Japanese Quaternary entomologists have insufficient data to meet these requests. However, our studies will continue, and new Quaternary entomologists will be trained.

This article is reproduced from the previous edition, volume 1, pp. 222–236, © 2007, Elsevier B.V.

Beetles are the most diverse group of organisms on Earth, and their exoskeletal remains preserve well in water-logged sediments of Pleistocene age. Studies of late Pleistocene fossil beetle assemblages have been carried out throughout many regions of North America in recent decades. This article reports on the major findings of these studies in terms of paleoenvironmental reconstructions and shifting distribution patterns (biogeography) of the species found in the fossil assemblages, all of which remain extant today.

The paleotemperature estimates reported here are derived from the mutual climatic range (MCR) of paleoclimate analysis, as discussed in the overview article for this section. For the sites in eastern and central North America, the MCR method was used to provide estimates of mean temperatures of the warmest ($T_{\max}$) and coldest ($T_{\min}$) months of the year. $T_{\max}$ and $T_{\min}$ estimates are discussed in terms of departures from the modern $T_{\max}$ and $T_{\min}$ of the study sites in question.

Research in Eastern North America

Pleistocene insect fossil studies began in earnest in the 1970s, with the most intensively studied region of North America being the central and eastern United States and southeastern Canada. Several fossil beetle assemblages in eastern North America are thought to represent Marine Isotope Stage (MIS) 5e, the last interglaciation. However, the ages of these fossil assemblages are tentative. One of the richest beetle faunas in this group is from Innerkip, Ontario (Figure 1, No. 1). This fauna includes several warm-adapted species, and MCR analysis of the fauna (Table 1) yielded an estimate of $T_{\max}$ that is essentially the same as modern parameters. The fossil assemblage from the Pointe-Fortune site on the southern Ontario–Quebec border (Figure 1, No. 2) is also thought to derive from MIS 5 (Anderson et al., 1990). This fauna contains boreal species that indicate colder than modern climate (Table 1), so perhaps it reflects a late MIS 5 environment. Likewise, faunal assemblages from the Henday site in northern Manitoba (Figure 1, No. 3) and the Owl Creek site in northeastern Ontario (Figure 1, No. 4) indicate climates that were colder than today (Table 1), based on the presence of Arctic ground beetles (Carabidae).

Assemblages from MIS 4 and 3 have been described from several localities in the Great Lakes region, as summarized by Elias (1994) and Ashworth (2004). MIS 4 assemblages from southeastern Canada contain tundra and tree-line beetle faunas. Faunal assemblages containing the same species also occur in regional MIS 2 assemblages, so it appears that tundra and tree-line species inhabited the margins of the Laurentide ice sheet continually during Wisconsinan time.

A series of insect faunas indicate changing conditions during the last (Wisconsin) glaciation. To date, late Pleistocene beetle assemblages have been published from 26 sites in this

region (Table 1). These range in age from >52,000 calibrated years before present (>52 ka) to 11.5 ka. The mid-Wisconsin interstadial, MIS 3, is thought to have lasted from approximately 65–25 ka. Isotopic data from Greenland ice cores and North Atlantic oceanic cores show multiple, abrupt climate changes during marine isotope stage 3 (Groote et al., 1993). Events within the first half of this interval cannot be dated by the radiocarbon method, and organic deposits that are stratigraphically correlated to the mid-Wisconsin interval are poorly dated in many regions of North America. The analysis of fossil beetle assemblages has progressed sufficiently in North America to allow reconstructions of the timing and intensity of MIS 3 climatic change (Elias, 1999).

Paleoenvironments of Central and Eastern North America during the Last Glaciation

The oldest MIS 3 beetle fauna considered here comes from the Chaudière valley, southeastern Quebec (Figure 1, No. 5). The fauna is associated with a mid-Wisconsin cold interval. Radiocarbon ages of this formation include a date of >54 ka. The sediments that yielded the fossils were underlain by a glacial till and overlain by late Wisconsin till. The beetle fauna is indicative of arctic tundra environments and includes many cold-adapted species. $T_{\max}$ was depressed by approximately 6 °C, and $T_{\min}$ was approximately 13 °C colder than today (Table 1).

The clearest indication of the strength of interstadial warming in eastern North America comes from the series of beetle faunal assemblages from Titusville, Pennsylvania (Figure 1, No. 6). The six fossil assemblages were deposited between approximately 46 and 43 ka. Within this interval, the Titusville faunas reflect climatic amelioration, followed by cooling. The oldest fauna (46.5 ka) indicates cooling of both $T_{\max}$ and $T_{\min}$ to approximately the same level as at the Chaudière valley site (Table 1). At the height of regional warming (ca. 45.7 ka), $T_{\max}$ was only 2 °C less than modern levels, and $T_{\min}$ was approximately 6 °C colder than modern. This warm interval occurred at approximately the same time as the Upper Warren Interstadial in Britain and the warm sea-surface temperature interval between Heinrich events 4 and 5 (Elias, 1999). By the end of the interstadial event (43.2 ka), regional climates had cooled to even lower levels than previously. Thus, in the space of approximately 3000 years, regional climates oscillated from subarctic to boreal and back again.

A beetle assemblage dated 38.5 ka from St. Charles, Iowa (Figure 1, No. 8), reflects prairie or savanna environments with patches of conifer–hardwood forest (Baker et al., 1991). The St. Charles beetle fauna was indicative of somewhat milder climate than during full glacial conditions but well below the levels of warming suggested by the interstadial fauna from Titusville. Later in the MIS 3 interval (32.9–28.9 ka), fossil

Figure 1 Map of eastern and central North America showing locations of fossil sites discussed in text. Site numbers match those in [Table 1](#).

assemblages from Illinois and Iowa indicate closed spruce forests. The sketchy picture that emerges for the early and mid-Wisconsinan is one of spatial and temporal heterogeneity in which populations of plants and insects were responding more dynamically than at any time during the Holocene ([Ashworth, 2004](#)).

By approximately 30 ka, the beetle evidence suggests that central North American climates had cooled to full-glacial levels ([Table 1](#)). $T_{\max}$ was approximately 10 °C colder than today at sites such as Athens and Wedron in Illinois ([Figure 1](#), Nos. 9 and 10). Regional faunas contained mixtures of boreal and arctic species, depending on latitude. Southerly sites, such as Salt Spring Hollow, Illinois ([Figure 1](#), No. 13), contained boreal beetle assemblages just before and during the Last Glacial Maximum (LGM). More northerly sites, such as Conklin Quarry, Iowa ([Figure 1](#), No. 15), contained beetles with Arctic and subArctic affinities.

In the mid-western region, Arctic beetles replaced the boreal forest fauna along the southern margin of the Laurentide ice sheet at approximately 25.8 ka. Colonization was probably from populations that dispersed southward in front of the growing ice sheet and from populations that dispersed westward and eastward from montane refugia in the Appalachian and Rocky Mountains, respectively ([Schwert and Ashworth, 1988](#)). From 25.8–17.7 ka, Arctic and subArctic species inhabited a discontinuous tundra zone along the margin of the ice sheet. Fossil assemblages typical of this time have been

reported from Iowa to New York ([Ashworth, 2004](#)). At the end of the glaciation, these cold-adapted faunas were forced to migrate in order to survive. Some species found refuge in high mountains, such as the Rocky Mountains in the west and the tops of the Appalachian Mountains in the east. Other species died out in the middle latitudes of the continent, and only their Beringian populations in ice-free regions of northwestern North America survived beyond the end of the Pleistocene.

The earliest sign of warming following the LGM comes from Weaver Drain, Michigan ([Figure 1](#), No. 18). This site was ice proximal at 17 ka, but MCR analysis ([Table 1](#)) shows that $T_{\max}$ had started to rise above the levels reconstructed from a 17.3-ka assemblage at Fort Dodge, Iowa ([Figure 1](#), No. 17). Ice proximal sites showed the effects of local cooling until the ice margin retreated and pockets of stranded dead ice melted, after approximately 12.6 ka.

By approximately 15.4 ka, substantial warming had occurred at Winter Gulf, New York ([Figure 1](#), No. 19). $T_{\max}$ values were less than 3 °C cooler than modern, and $T_{\min}$ values were less than 5 °C cooler than modern. This degree of warming was not seen in the oldest assemblages from Gage St., Ontario ([Figure 1](#), No. 20). However, during the interval 14.5–12.8 ka, $T_{\max}$ and $T_{\min}$ at Gage St. rose above modern levels ([Table 1](#)). This was also the case at Nichols Brook, New York ([Figure 1](#), No. 26) and Rostock, Ontario ([Figure 1](#), No. 21) between 13.3 and 11.5 ka.

Between approximately 12.9 and 11.5 ka, a third set of sites (St. Eugene and St. Hilaire, Quebec, Eighteen Mile River, Ontario, and Lockport Gulf, New York) were situated near large bodies of glacial meltwater (proglacial lakes and the Champlain Sea). The large bodies of chilled water adjacent to these sites strongly affected local climates (Ashworth, 2004). After 11.5 ka the ice sheet margin had retreated well north of the study sites, and all the fossil assemblages reflect $T_{\max}$ values near modern parameters (Table 1).

Beetle MCR reconstructions from northwest Europe show a sudden rise in seasonal temperatures by approximately 15.9 ka, followed by a general cooling through the Late Glacial interstadial, before dramatic cooling at 12.9 ka (the Younger Dryas chronozone), followed by a sudden rise in temperatures at approximately 11.5 ka (Coope and Lemdahl, 1995). The eastern North American results show almost a plateau of summer temperatures from 13–10 ka. The vegetation history, as reconstructed from fossil pollen assemblages, also suggests no climatic reversals during this interval (Grimm and Jacobson, 2004). The lack of oscillations in the North American assemblages may be due to the effects of continental climate, whereas Late Glacial climates in northwest Europe were strongly affected by shifts in North Atlantic surface water (Coope and Lemdahl, 1995). The only insect evidence for cooling between 12.9 and 11.5 ka in North America comes from the maritime provinces of Canada (Walker, et al., 1991) and from Arctic Alaska.

Research in Western North America

Late Pleistocene beetle assemblages have also been studied from a number of sites in western North America (Table 2). Insect fossils of this age from the Rocky Mountain region are discussed by Elias (1990, 1991). Full glacial age faunas, such as the assemblage dated 17.7 ka from Lamb Spring, Colorado (Figure 2, No. 1), indicate that $T_{\max}$ was 10–11 °C colder than today. The earliest evidence for the start of postglacial warming is a 16.9-ka assemblage at the Mary Jane site in Colorado (Figure 2, No. 2). Rapid warming occurred after 13.3 ka, with summer temperatures becoming warmer than present by 11.5 ka at False Cougar Cave, Montana (Figure 2, No. 4). Many of the cold-adapted species in the late Pleistocene Rocky Mountain fossil assemblages have since retreated upslope to the Alpine tundra, but not all species were able to do this. For instance, the cold-adapted rove beetle, *Holoboreaphilus nordenskiöldi*, was found in a Late Glacial age assemblage from Marias Pass, Montana (Figure 2, No. 3). This species apparently died out in the Mid-Latitudes at the end of the last glaciation. It is found today only in Arctic North America (Elias, 1991).

In the past 20 years, insect fossils from arid regions of the southwestern United States and northern Mexico have received intensive study. These studies are based on fossil remains extracted from packrat (*Neotoma*) middens. Packrat middens are caches of objects, including edible plants, cactus spines, insect and vertebrate remains, small pebbles and feces, brought to the rat's den site for a variety of reasons, including food, curiosity, and den protection; then they are cemented into black tarry masses by packrat urine. Late Pleistocene insect fossils have been studied from the Great Basin, but the most

intensively studied region is the Chihuahuan Desert (Figure 3). Most packrat midden beetle assemblages from the Sonoran Desert date to the Holocene.

Late Pleistocene faunas from the arid southwest were mixtures of temperate and desert species not seen in any one region today. Since the end of the Pleistocene, some of these species have become established in different desert regions (Elias, 1992). Others now live outside the desert zone, in temperate regions. The fossil insect record indicates that even sedentary, flightless beetles (e.g., the heavy-bodied weevils) have undergone marked distributional shifts in the American southwest within the space of a few centuries. Moreover, even highly specialized cave dwellers have somehow managed to move from one cave system to another in response to changes in late Wisconsin and Holocene environments.

Late Pleistocene beetle assemblages from the southern Chihuahuan Desert of Mexico (Figure 2, Nos. 21 and 22) contain mixtures of desert and temperate zone species (Elias et al., 1995). Midden assemblages from locations farther north in the Chihuahuan Desert are generally separated into glacial age faunas with temperate zone affinities and postglacial faunas with desert zone affinities. Faunal assemblages with no modern analog are indicative of the late Quaternary environments unlike any that exist today. This conclusion is also borne out by the plant macrofossil record.

The insect faunas from the Big Bend region of southwest Texas (Figure 2, Nos. 8, 10, 12, 17, and 19) suggest that there was greater effective moisture from 35–14 ka (Elias and Van Devender, 1990). During the late Wisconsin (MIS 2), many temperate grassland species lived in the Big Bend region. After 14 ka, most of these species were replaced by either desert species or more cosmopolitan taxa. The faunal change suggests a climatic shift from cool, moist conditions of full glacial times to hotter, drier conditions during the Late Glacial and early Holocene.

In the northern Chihuahuan Desert, full glacial (26.5–21.6 ka) faunal assemblages (Figure 2, Nos. 5, 6, 14–16, 23, and 24) suggest widespread coniferous woodland at elevations as low as 1200–1400 m above sea level (Elias and Van Devender, 1992). These woodland environments persisted until 12.9 ka, but the insect data suggest considerable open ground, with grasses at least locally important at the midden sites. The grassland nature of the arthropod fauna was also suggested in the regional vertebrate record. The transition from the temperate Wisconsin fauna to the more xeric postglacial fauna started by 14.8 ka. The timing of this faunal change was essentially synchronous throughout the region. A major difference between the Big Bend and northern Chihuahuan Desert scenarios is the nature of this faunal change. In the Big Bend region, the transition was characterized by the disappearance from the record of all but one of the temperate insect species by approximately 14 ka. However, the xeric-adapted fauna did not appear in the Big Bend records until approximately 8.3 ka. In the northern Chihuahuan Desert assemblages, the xeric species first appeared at 14.8 ka, and several of the temperate grassland species from the Wisconsin interval persisted well into the Holocene. This mixture of xeric and temperate elements makes ecological sense because these northern faunas were living close to the edge of the Chihuahuan Desert. The gradual shifting of northern desert boundaries in postglacial times

Figure 2 Map of western North America showing locations of fossil sites discussed in text. Site numbers match those in [Table 2](#).

probably created many marginal habitats for temperate species in ecotones between grassland and desert scrub.

Work on late Quaternary insect faunas from the Colorado Plateau region ([Figure 2](#), Nos 7, 9, 11, 13, and 20) suggests that late Wisconsin climatic conditions there were cooler and moister than present, and that the plateau supported a mosaic of grassland and shrub communities without modern analog ([Elias et al., 1992](#)).

MCR analysis of arid southwestern faunas ([Elias, 1998](#)) suggests that effective moisture exerts greater control on desert beetle distributions than does temperature. The author's MCR analysis of late Pleistocene beetle assemblages from the Mojave Desert ([Elias](#), unpublished data) indicates that $T_{\max}$ was 7–8 °C cooler than it is today from 38–36 ka, and mean annual precipitation (MAP) was 3.5–4.4 times greater than it is today. In the eastern Great Basin, the Bonneville Estates site yielded a beetle fauna dated 13.6 ka. Several of the species in this fauna are found today in the Pacific Northwest region. MCR analysis of this fauna indicated that $T_{\max}$ was 5–6 °C cooler than today, and MAP was 525–675 mm, compared to modern MAP at the site of approximately 190–210 mm. These results agree well with paleoclimate reconstructions based on ancient pluvial lake levels ([Benson, 2004](#)) and regional paleobotany ([Thompson et al., 2004](#)).

[Miller \(1983\)](#) discussed insect fossil assemblages from California asphalt deposits at McKittrick ([Figure 2](#), No. 29)

and at Rancho La Brea in Los Angeles. The Rancho La Brea assemblages remain undated; the late Pleistocene McKittrick fauna dates to approximately 14.3 ka. Unlike the faunas of most other regions discussed here, the McKittrick and Rancho La Brea assemblages reflect conditions similar to those in southern California today.

[Nelson and Coope \(1982\)](#) described a diverse insect fauna dating from 18 ka from Seattle, Washington ([Figure 2](#), No. 28). Although the pollen spectra associated with this assemblage suggest conditions substantially colder than present, the insects are characteristic of the modern Puget lowland. Nelson and Coope suggest that the discrepancy between the flora and insect fauna may be due to increased climatic continentality just before the last glacial advance. MCR analysis of this assemblage ([Table 2](#)) suggests that $T_{\max}$ was 1–3 °C colder than modern at the site, and that $T_{\min}$ was considerably colder than modern.

[Cong and Ashworth \(1996\)](#) described a beetle fauna from the Kalaloch site in northwest Washington ([Figure 2](#), No. 25). This fauna dates from 24.1–20.5 ka, and MCR analysis indicates that summer temperatures were only slightly cooler than today ([Table 2](#)). Most of this fauna can be found today in the lowlands of the Pacific Northwest, but a few species are restricted today to the northern boreal forest regions ([Ashworth, 2004](#)).

In southern British Columbia, [Miller et al. \(1985\)](#) studied insect fossils from 22.6–22.1 ka at Mary Hill and Port Moody

Figure 3 Scanning electron micrographs of late Pleistocene fossil beetle specimens from the Chihuahuan Desert. (Figure 2, Nos. 26 and 27). These assemblages represent an open coniferous forest floor community, developed in cool, dry climatic conditions between two advances of the Cordilleran ice sheet.

Throughout western North America, both temperature and precipitation regimes changed dramatically throughout the late Pleistocene. These climatic changes brought about wholesale changes in regional ecosystems, as reflected in the fossil beetle record. Unlike eastern North America, the western regions are topographically diverse, with dozens of mountain ranges interspersed with valleys, canyons, and flatlands. Cold-adapted beetles dominated many late Pleistocene faunal assemblages, expanding their ranges downslope and southward

in response to climatic cooling, then retreating upslope and northward in response to warming.

Research in Eastern Beringia

During the late Pleistocene, eastern Beringia comprised the unglaciated regions of Alaska and the Yukon Territory. This region was an important refuge for arctic biota, including insects. Because of preservation in permafrost, the fossil beetle record of this region extends back into the late Tertiary. The nature of Pleistocene environments in eastern Beringia is a topic of considerable debate. Some patterns concerning

*Coastal sites with unreliable reconstructions of TMIN. See text for discussion.

Beringian paleoenvironments are beginning to emerge, but our reconstructions are far from complete. When I reported on the state of Pleistocene insect fossil research in this region in 1994, I noted that ‘an enormous amount of work is yet to be done.’ Although our knowledge has increased in the past decade, the statement remains equally true today. The following discussion deals with published fossil data from 28 sites (Table 3, Figure 4). The evidence has been reviewed most recently by Elias (2000, 2001) and Ashworth (2004).

Based on their stratigraphic position, a number of fossil beetle assemblages can be confidently placed in MIS 6 (Table 3), including assemblages from the Old Crow site (Figure 4, No. 1), Chi’jee’s Bluff (Figure 4, No. 2), and Kulukbuk Bluffs (Figure 4, No. 3). These faunas reflect climates with depressed summer temperatures, but some sites yielded MCR estimates of $T_{\min}$ that are near modern levels. Based on stratigraphic relationships with sediments containing the Old Crow tephra (dated 140 ka), several beetle assemblages from Alaska and the Yukon indicate that prior to the onset

of full interglacial conditions in MIS 5e, temperatures were beginning to warm. This evidence comes from several sites on the Noatak River in northwestern Alaska (Figure 4, Nos. 4–6) and the Nuyakuk site in southwestern Alaska (Figure 4, No. 7). Full interglacial warming peaked at levels that varied from region to region. In southwestern Alaska, the height of MIS 5e amelioration was as much as 3.5 °C warmer than modern at the Nuyakuk site. At the NK-37 site in northwestern Alaska, $T_{\max}$ climbed to as much as 4.5 °C above modern levels. Further east, summer temperatures were probably closer to modern levels. The best constrained estimate of average winter temperatures during MIS 5e comes from Chi’jee’s Bluff. This estimate suggests that $T_{\min}$ was approximately 4–7 °C warmer than today, even though average summer temperatures at this site may have been slightly cooler than modern. Boreal insects and paleobotanical evidence combine to document the presence of coniferous forests in much of eastern Beringia during MIS 5e.

Figure 4 Map of northwestern North America showing locations of fossil sites discussed in text. Site numbers match those in Table 3.

(a) Left elytron of *Tachinus brevipennis*; (b) elytra of *Vitavitus thulius*; (c) right elytron of *Elaphrus parviceps*; (d) head and pronotum of *Harpalus amputatus*; (e) head, pronotum, and elytra of *Connatichela artemisiae*; (f) pronotum of *Pterostichus brevicornis*; (g) pronotum of *Pterostichus pinguedineus*; (h) pronotum of *Amara alpina*; (i) pronotum and right elytron of *Morychus* sp.; (j) head of *Lepidophorus linneaticollis*; (k) pronotum and elytron of *L. linneaticollis*; (l) left elytron of *Pterostichus nearcticus*. Scale bars = 1 mm.

Beetle faunas associated with younger intervals of MIS 5 have yielded MCR estimates showing climatic cooling, with $T_{\max}$ levels declining 2–3 °C below modern parameters (Table 3). Two faunas thought to derive from MIS 4 indicate that summer temperatures continued to cool. The MIS 4 faunal assemblage from Hungry Creek, Yukon (Figure 4, No. 9), yielded a $T_{\max}$ estimate 6–9 °C cooler than modern.

The long MIS 3 interstadial complex in eastern Beringia is represented by 25 faunal assemblages from 18 different sites. Warming intervals are indicated by faunas from the Titaluk River in northern Alaska (Figure 4, No. 12) (46.4, 36, and 33.6 ka), from Cape Deceit on the Seward Peninsula (Figure 4, No. 14) (42.2 ka), and from Kulukbuk Bluffs in southwestern Alaska (35 ka). The strongest indication of interstadial warming comes from the Titaluk River fauna dated 33.6 ka. This fauna

yielded a $T_{\max}$ estimate 0.5–2 °C warmer than modern. The other faunas discussed previously yielded $T_{\max}$ estimates that were 0.5–2 °C cooler than modern. Interestingly, a fauna dated 31.5 ka from Mayo Village, Yukon (Figure 4, No. 18), indicates that regional $T_{\max}$ had fallen to 5–6 °C colder than modern levels. Likewise, a fauna dated 35.2 ka from Eva Creek, interior Alaska (Figure 4, No. 8), indicated $T_{\max}$ levels 7–8 °C colder than modern. Thus, within the space of 2,000 years, temperatures appear to have oscillated dramatically in eastern Beringia. The beetle faunas that yielded the indications of interstadial warming are composed of species found today in open-ground habitats within the boreal forest. They do not rely on the presence of trees. The paleobotanical evidence suggests that most if not all of eastern Beringia remained open-ground tundra or steppe–tundra throughout MIS 3.

During the LGM, the beetle evidence indicates that $T_{\max}$ was depressed in eastern Beringia, but that $T_{\min}$ was within 1–2 °C of modern levels in most regions. Elias et al. (1999) discussed difficulties in reconstructing $T_{\min}$ from faunal assemblages sampled from coastal sites. First, the ancient coastline of Beringia was removed from its current position by more than 1000 km in some regions. Therefore, the modern $T_{\min}$ of a coastal site, greatly influenced by maritime climate, bears little relation to the ancient climate of the same site when it was hundreds of kilometers inland because of lowered sea level. Also, even the modern $T_{\min}$ of coastal sites is a poor reflection of winter temperatures at these sites because of the incursion of Arctic air masses during the winter season. These periods of very low temperature are sufficiently long, and sufficiently frequent, to virtually eliminate the less cold-resistant beetle fauna of coastal Alaska.

Following the LGM, beetle faunas from throughout eastern Beringia are indicative of climatic amelioration, beginning by at least 15.3 ka. This warming is especially noteworthy in the Arctic zone, where $T_{\max}$ rose above modern levels during the Late Glacial interval. The warming indicated by faunas from the subArctic zone is less marked during this interval. There is also evidence, again from the Arctic assemblages, for a brief climatic oscillation during the Younger Dryas chronozone (Elias, 2000).

Two principal ecosystems appear to have dominated eastern Beringia during late Pleistocene glacial periods: steppe–tundra and mesic tundra. Steppe–tundra, or ‘mammoth steppe’ as Guthrie (1990) described it, was rich in grasses and sagebrush (*Artemisia*). It supported a diverse, abundant megafauna of grazers and their predators. In Alaska and the Yukon, this ecosystem also had a characteristic beetle fauna, dominated by the ground beetles *Amara alpina* (Figure 5(h)) and several species of *Harpalus* (Figure 5(d)) pill beetles (Byrrhidae) in the genus *Morychus* (Figure 5(i)), dung beetles in the genus *Aphodius*, and the weevils *Lepidophorus lineaticollis* (Figures 5(j) and 5(k)) and *Connatichela artemisiae* (Figure 5(e)). This steppe–tundra fauna, first recognized by Matthews (1983), is commonly found in fossil assemblages throughout the Yukon and interior Alaska. However, in other regions of Alaska, a different suite of beetle taxa dominate late Pleistocene assemblages. This group includes the *Cryobius* group of ground beetles in the genus *Pterostichus* (Figures 5(f) and 5(g)), several other ground beetles associated with mesic and moist habitats, rove beetles in the subfamily Omaliinae, and weevils that feed on dwarf birch and dwarf willow. This mesic tundra fauna has been found in fossil assemblages throughout southwestern and northwestern Alaska, as well as in samples taken from the ancient Bering Land Bridge that connected Alaska to Siberia during intervals of lowered sea level (Elias et al., 2000). The land bridge may have served as a biological filter, keeping dry-adapted species, such as the woolly rhinoceros, from entering North America (Guthrie, 2001).

Conclusions

Late Pleistocene beetle assemblages from sites throughout North America have documented large-scale, rapid climatic changes. During MIS 3, beetle assemblages have demonstrated

oscillating interstadial warming and cooling events that coincide with climatic patterns inferred from oxygen isotope records in Greenland ice cores. The pace and severity of such changes have often gone undetected in paleoenvironmental reconstructions based on fossil pollen, although new analytical methods are making breakthroughs (Grimm and Jacobson, 2004). As has been noted in the history of the European beetle fauna (Coope, 1978), North American beetles appear to have responded to the vagaries of Pleistocene climates by shifting their distributions in order to stay within climatic conditions to which they are best adapted. Thus, the Pleistocene beetle fauna of North America remains extant today, albeit living in different regions. Each new climatic regime of the Pleistocene brought new associations of species together in a given region. Many of the species in given types of associations remained constant through long stretches of time, but different species were added or subtracted from the fauna of any specific region as ecosystems waxed and waned.

Late Pleistocene of South America

A C Ashworth, North Dakota State University, Fargo, ND, USA

This article is reproduced from the previous edition, volume 1, pp. 212–221, © 2007, Elsevier B.V.

Background

Studies of fossil beetle assemblages in South America have been directed at coming to a better understanding of how beetles respond to climate change and to the use of that information for interpreting paleoclimate. One of the primary challenges of the research has been to demonstrate that the results would be sufficiently robust for other researchers in archaeology, plant paleoecology, glacial geology, and paleoclimatology to use with confidence in their studies. Of particular interest has been the question of whether a climatic reversal occurred in southern South America that was of similar magnitude and timing to the Younger Dryas interval defined from the North Atlantic region. The sites from which Pleistocene fossil assemblages have been studied in South America are located primarily in the Chilean lake region and the Chilean channels, between 40 and 50° S (Figure 1). A single fossil assemblage of early to mid-Holocene age has also been examined from the Falkland Islands in the Atlantic Ocean between 51 and 52° S (Buckland and Hammond, 1997).

The Landscape of Southern Chile

In the Región de Los Lagos (lake region), the terrain is mountainous with the Cordillera de la Costa (coastal ranges) separated from the stratovolcanoes of the Cordillera de los Andes (Andes) by a wide north–south trending lowland, the Valle Longitudinal (central valley). Dense forests once cloaked the entire landscape of the lower elevations but have mostly been cleared for agriculture. Today, extensive tracts of native Valdivian and North Patagonian rain forests survive only at higher elevations in the lake region (Figure 2(a)). Above treeline, the forests are replaced by an Andean tundra (Figure 2(b)) that extends to the fell fields, and permanent snow and ice capping the higher volcanic peaks. Further south in the Chilean channels, the landscape is more fragmented. Island archipelagoes, crisscrossed by deep glacially excavated fjords, extend to the tip of the continent. The permanent snow line is lower, and outlet glaciers of the North and South Patagonian ice fields calve icebergs into the fjords (Figure 3(a)). The lowland vegetation is a dense cold-temperate rainforest (Figure 3(b)) which, at higher elevations, is replaced by the saturated soils and blanket bogs of the Magellanic moorland (Figure 3(c)). The climate in southern South America, from the mid- to the high latitudes, is dominated by a westerly circulation stronger in the south than in the north. Whitlock et al. (2001) discuss the relationship between climate, vegetation, and the insect fauna.

The Existing Beetle Fauna

The beetle fauna of the forests, moorlands, and steppes of southern South America is unusually rich in endemic taxa.

Endemism implies ancient evolutionary relationships and Patagonia is the home of many surviving lineages of ancient clades. The Migadopini, for example, are an exclusively Southern Hemisphere tribe of Carabidae (ground beetles) that have a typically Gondwanan distribution. They occur throughout southern South America, including the Falkland Islands, Tasmania and southeastern Australia, and New Zealand and the Auckland Islands. Similar restricted geographic distributions occur within several families of beetles in the southern South American fauna, notably the Protocujidae, Chalcodryidae, Nemonychidae, and Belidae. These groups are either monotypic or represented by a small number of genera that are associated with *Nothofagus* forest. The taxa in many of these families evolved during the late Cretaceous when southern South America was still connected to Antarctica. The connection was severed by seafloor spreading to form the Drake Passage between 34 and 30 Ma. The recent discovery of fossils of listroderine weevils in Neogene deposits, 500 km from the South Pole, confirms the evolutionary ties that South America had with Antarctica (Ashworth and Kuschel, 2003). Listroderine weevils are presently widely distributed in the forests, steppes, and moorlands of southern South America.

Joseph Banks, naturalist on the HMS Endeavour, Captain James Cook's first voyage of exploration, collected beetles from southern South America in 1769. One of those specimens, the ground beetle *Ceroglossus suturalis*, was described by Johann Fabricius in 1775. In the nineteenth century, Charles Darwin and other naturalists, who followed, sent their specimens back to Europe to be described by specialists in the natural history museums in London and Paris. Darwin was responsible for collecting one of the most distinctive beetles of the Chilean rain forest, the lucanid *Chiasognathus grantii* Stephens. The male is characterized by mandibles that are almost twice as long as its body (Figure 4(a)) giving rise to its common name in southern Chile of 'ciervo volante' or 'flying deer.' In *The Descent of Man*, Darwin wrote 'But the mandibles were not strong enough so as to cause actual pain.' The specimens are preserved in the Natural History Museum, London, where the male is known as 'the beetle that bit Darwin.' The nineteenth century naturalist who made the greatest contribution to the knowledge of the Chilean fauna was Claudio Gay. He made extensive collections of the fauna during travels between 1828 and 1842, and those specimens are described and illustrated in color in his 1849 and 1851 volumes of *La Historia Física y Política de Chile* (Figure 4(a)). More recently, Elizabeth Arias (2000) has described the most distinctive species of the fauna in *Coleópteros de Chile*.

There are numerous excellent taxonomic treatments of the existing beetle fauna which are invaluable as aids in the identification of Pleistocene fossils. There are few faunistic and ecological studies, however, on which to base paleoenvironmental and paleoclimatic interpretations. Ashworth and Hoganson (1987) made extensive collections in the Parque

Figure 1 Location of fossil beetle assemblages from southern South America. The representation of the Patagonian ice sheet during the last glaciation is from [Hollin and Schilling \(1981\)](#).

Nacional Puyehue and other undisturbed habitats in the Chilean lake region ([Figure 4\(b\)](#)). They described a diverse fauna of 462 species from habitats collected systematically along an elevational transect from sea level to 1200 m. Their ordination analysis showed changes in beetle communities along the transect which generally correlated with changes in vegetation.

Fossil Studies

Chilean Lake Region

In the Chilean lake region, fossil assemblages ranging in age from 24,000 to 4,525 ka BP have been examined. Assemblages from sites at Puerto Octay, Puerto Varas (Park and Railroad), Rio Caunahue, and Monte Verde have been described and their significance discussed in a series of papers ([Hoganson et al., 1989](#); [Hoganson and Ashworth, 1992](#); [Ashworth and Hoganson, 1993](#)). Additionally, unpublished fossil assemblages have been studied by Ashworth from sites at Rupanco, Dalcahue, and Puerto Varas (Loreley and Calle Santa Rosa) ([Figure 1](#)). All of the sites, with the exception of Monte Verde, are from locations in the lowlands of the central valley that were glaciated during the Last Glacial Maximum. The Monte Verde site is

located west of the terminal moraines of the last glaciation and is associated with a drainage that developed on glacial outwash.

The oldest fossil beetle assemblages to have been examined are from peat deposits near the west end of Lago Rupanco ([Figure 1](#)). Fossils were extracted from an *in situ* peat that is overlain by gravel, till, and volcanic deposits ([Mercer, 1976](#); [Denton et al., 1999](#)). The assemblages range in age from 19 500 to 24 000 yr BP and are representative of the beetle fauna of the lake region immediately prior to the Last Glacial Maximum. The assemblages are the least diverse of any examined from the lake region consisting of only 9–10 species. Exceptionally well-preserved skeletal parts of the listroderine weevil *Germaniellus dentipennis* (Germain) ([Figure 5](#)), including heads, pronota, elytra, sternites, leg segments, and genitalia, make up 90% of the fossils.

Similar assemblages dominated by *G. dentipennis* occur within the lake region until about 14 000 to 14 500 yr BP. The youngest of these assemblages, dated at 14 340 yr BP, is from near Dalcahue on La Isla Grande de Chiloé (Chiloé). The peaty deposits are overlain by outwash gravels and till of the final major glacial advance in the mid-latitudes of South America ([Figure 6](#)). Included in the 22 taxa from this

Figure 2 Habitats in the Chilean lake region: (a) The lower Valdivian rain forest in the lake region near Aguas Calientes, Parque Nacional Puyehue; (b) the Andean tundra and krummholz at treeline east of Antillanca, Parque Nacional Puyehue. Volcán Casablanca is in the background. Photographs by A. C. Ashworth.

assemblage is the weevil *Paulsenius carinicolis* (Blanchard) and the ground beetle *Cascellius septentrionalis* Roig-Juñent that today both inhabit higher elevations in the Andes. Villagrán (1990) made the observation that Magellanic moorland plants, which currently inhabit relict patches at 700 m elevation in the coastal ranges of Chiloé, grew near sea level during the last glaciation Villagrán (1990). Using an adiabatic lapse rate of $0.65^{\circ}\text{C}/100\text{ m}$, Ashworth and Hoganson (1993) estimated that mean summer temperature during the glacial interval was $4\text{--}5^{\circ}\text{C}$ lower than today based on the species composition of fossil beetle assemblages. Denton et al. (1999) estimated that snow and treeline were lowered by 1000 m between 29 400 and 14 400 yr BP representing mean summer temperatures $6\text{--}8^{\circ}\text{C}$ lower than today.

Fossil assemblages postdating 14 000 yr BP are fundamentally different in their composition. Not only are they considerably more diverse but also contain higher percentages of taxa that are obligate forest inhabitants. Most of the assemblages that have been examined are from exposed cut bank sections on the Rio Caunahue, a large river that originates in the Andes and enters Lago Ranco on the east side. Rhythmically laminated deposits containing abundant organics and volcanic ashes were deposited in a narrow arm of the lake immediately following deglaciation (Figure 7(a)). The basal sediments are inorganic

Figure 3 Habitats in the Chilean channels: (a) The Glaciar Pio XI in the Chilean channels; (b) dense rainforest of *Nothofagus betuloides* in the Fiordo Bernardo. (c) Magellanic moorland in the coastal mountains west of Puerto Edén. Photographs by A. C. Ashworth.

clays representing the deposition of rock flour. The 7-m sequence, with a basal age of 13 900 yr BP (Ashworth and Hoganson, 1993), contains exceptionally well-preserved fossils (Figure 7(b)). The species compositions of 30 intervals pre-dating 10 000 yr BP were reported in Hoganson and Ashworth (1992); the number of taxa identified was 154, of which 41–48% consisted of obligate forest taxa. All of the taxa currently inhabit the forests of the lake region, mostly the Valdivian rain forest.

The only other fossil beetle assemblage post-dating 14 000 yr BP that has been examined from the lake region is

Figure 4 Modern beetle fauna: (a) Enlargement of one of the plates from Gay's nineteenth-century *Historia Física y Política de Chile*. The beetle with the large mandibles is the distinctive Valdivian rain forest lucanid *Chiasognathus grantii*; (b) studies of the modern beetle fauna were essential to establishing the base for paleoclimatic interpretation. Photograph by A. C. Ashworth.

from the archaeological site at Monte Verde, near Puerto Montt (Figure 8). At Monte Verde, humans are believed to have constructed primitive shelters and hunted mastodon. Fossil beetles were retrieved from horizons considered to be contemporaneous with the human habitation (MV-6) dated between 13 565 and 11 790 yr BP, and also from a peat bed (MV-5) that

Figure 5 The weevil *Germainiellus dentipennis* (Morrone, 1993) whose exoskeletal remains are the most abundant in fossil assemblages dating from 24 000 to 14 000 yr BP. Reproduced from Morrone JJ (1993) Revisión sistemática de un nuevo género de Rhytirrhini (Coleoptera, Curculionid), con un análisis biogeográfico del dominio subantártico. *Boletín de la sociedad de Biología de Concepción, Chile*, 64: 121–145.

sealed the cultural horizon and is dated between 11 810 and 10 860 yr BP (Dillehay and Pino, 1989). Statistical comparison of the 95 taxa occurring in MV-6 and MV-5 demonstrated that the assemblages were similar to one another (Hoganson et al., 1989).

Using cluster analysis, the species compositions of the fossil assemblages were compared to modern communities from 41 locations within the Chilean lake region. The Monte Verde assemblage was most similar to the communities from slightly disturbed coastal forests and from the Valdivian Rain Forest at about 500 m elevation (Hoganson et al., 1989). The interpretation that the paleoclimate at Monte Verde was essentially similar to that of today during the human occupation is consistent with interpretations from similar-aged fossil beetle assemblages at the Rio Caunahue site.

One of the intriguing puzzles of the Monte Verde beetle assemblage is that no synanthropic beetles were identified. In Europe, fossil beetle assemblages from archaeological sites ranging in age from Mesolithic to historical times show evidence of modification, especially those associated with agricultural. Why there would be no synanthropic insects at Monte Verde is unknown, but it is possible that hunter-gatherer groups did not disturb the natural environment to such an extent that it caused an ecological response in the beetle fauna. A similar observation was made for early Postglacial beetle faunas associated with human occupation in North America (Elias, 1994).

To examine longer-term trends represented by the fossil beetle assemblages, the total taxa and the ratio of taxa dependent on trees are examined for 1 ka intervals between 24 000 and 9 000 yr BP (Figure 9(a)). The beetle fauna from 24 000 yr BP to the time of the last glacial advance about 14 000 yr BP was composed of species of wet moorland habitats. The assemblages are characterized by low diversity and low numbers of taxa dependent on shrubs and trees. Between 14 000 and 13 000 yr BP the diversity is low but the percentage of arboreal taxa is higher. Between 13 000 and 12 000 yr BP, the assemblages are at least 5 times as diverse as those of the glacial interval. The changes indicate that by 13 000 yr BP, moorland

Figure 6 (a) At Dalcahue, Isla Grande de Chiloé, organic sediments (brown) contain the youngest fossil beetle assemblages representing the glacial beetle fauna. Fossil wood at the top of the section (by the knife) has an age of 14.34 ka BP; (b) organic sediments accumulated in a small depression on the surface of a weathered till. The surface was buried by outwash gravel (top of the section) during the last glacial advance in the lake region. Scale = cm divisions. Photographs by A. C. Ashworth.

Figure 7 (a) The Rio Caunahue assemblages are from laminated silts interbedded with volcanic ashes. The bench on which the person is standing has an age of 12.81 ka BP and the prominent white volcanic ash above his head has an age of about 10.8 ka BP. (b) The fused fossil elytra (wing cases) of a specimen of the ground beetle *Ceroglossus*, that is from the horizon dated at 10 ka BP. (c) A modern specimen of *Ceroglossus* from the Valdivian rain forest. Scale bars = 5 mm. Photographs by A. C. Ashworth.

habitats, which had existed in the central valley for more than 10 000 yr, had been replaced by forested habitats similar to those that exist in the region today.

The numerical data are also used to test two null hypotheses (Figure 9(b)). The first is that no relationship exists between

total taxa and ratio of arboreal taxa. This hypothesis was tested using linear regression ($\alpha = 0.05$). The null hypothesis was shown not to be true, and the relationship between total taxa and ratio of arboreal taxa was found to be highly significant ($P = 0.001$, $r^2 = 0.62$). The interval from 14 000 to 13 000 yr

Figure 8 The Monte Verde archaeological excavation. An excavated hearth-like structure is visible in the foreground. The peat MV-5 which contains abundant fossil beetles and is dated between 11.81 and 10.86 ka BP is visible at the base of the cut on the far wall of the excavation. Photograph by A. C. Ashworth.

BP has a studentized residual value of 11.5 making it very different from all other samples. The difference is explained because the sample represents most of the change in the transition between moorland and forested biomes.

The second null hypothesis is that no significant difference exists between the ratios of arboreal taxa for two subsets of samples between 24 000–15 000 yr BP and 13 000–9 000 yr BP. The sample representing the 13 000–14 000 yr BP interval was not included in the test because it is a statistical outlier. The null hypothesis was tested using a two-sample T-test ($\alpha = 0.05$). The result was that the null hypothesis was shown not to be true. The ratios of arboreal taxa to total taxa for the glacial interval 24 000–15 000 yr BP are significantly different than for the postglacial interval between 13 000 and 9 000 yr BP ($t = 9.842$, $df = 8.5$, $P < 0.001$).

Chilean Channels

Fossil beetle assemblages have been examined from two locations in the Chilean channels. The Puerto Edén site on the Canal Messier is from an excavation in a bog (Figure 10), and the Témpano Sur site is from an outcrop in the wall of an abandoned meltwater channel about 1 km from the margin of the Glaciar Témpano, an outlet glacier of the South

Figure 9 Longer-term trends for the interval 24–9 ka BP represented by a compilation of data from all of the fossil assemblages: (a) plots of the total number of taxa (bar graph) and the ratio of obligate arboreal taxa (line graph); (b) the relationship between total and ratio of arboreal taxa. The x-axis is natural log transformed. The labels shown are mid-ranges for samples, each of which represents a 1 ka interval of time. The line represents a significant linear regression. The data point at 13.5 (14–13 ka BP) is a significant outlier representing the time of major change between moorland and forest assemblages.

Figure 10 The bog at Puerto Edén is located between morainic arcs deposited by a glacier that retreated into the coastal ranges. Glacial ice also filled the Paso del Indio, the marine channel that leads northward to the Messier Canal. Photograph by A. C. Ashworth.

Patagonian ice field (Figure 11). At both sites, pollen and fossil beetles were examined from the same samples (Ashworth and Markgraf, 1989; Ashworth et al., 1991). As the glacier at Puerto Edén receded westward to the coastal mountains, peat began to accumulate at about 13 000 yr BP in a shallow depression

Figure 11 The fossil site at Témpano Sur is located behind the bedrock ridge in the foreground. It is located in an abandoned meltwater channel that has an outlet to the fjord at the extreme right of the photograph. The floating ice is from melting of the Glaciar Témpano about 1 km to the left of the image. Photograph by A. C. Ashworth.

between morainal ridges. Throughout the peat profile there is excellent agreement between the interpretations based on fossil beetles and those based on pollen (Ashworth et al., 1991). Immediately following deglaciation, the colonizing plants and beetles were those of open ground communities, similar to those inhabiting active glacial outwash plains about 45 km east of the site. From 13 000 to about 9 500 yr BP the biota was that of a *Nothofagus* woodland which persisted until 5 500 yr BP, when it was replaced by a rainforest-moorland mosaic similar to that existing in the region today. Sometime between 5 500 and 3 000 yr BP, the biota changed dramatically on the moraines surrounding the bog, and the bog itself dried up. After 3 000 yr BP, a biota similar to that which had existed between 9 500 and 5 500 yr BP returned. Puerto Edén has a precipitation of about 3000 mm yr⁻¹. For the bog to completely dry up requires a very significant climatic change. Markgraf et al. (2003) reported changes in the sedimentology, paleontology, and geomorphology of Lago Cardiel (49° S) on the Patagonian steppe, east of Puerto Edén indicating severe droughts between 6000 and 5000 ka BP. They point out that widespread mid-Holocene aridity has been reported in records from the Patagonian steppe to the North American plains, but for which, as yet, there is no compelling climatological explanation.

At the head of the Témpano fjord, interbedded sands and peats infilled a bedrock-floored channel that was later eroded by meltwater. The basal peat is dated between 11 180 and 10 130 yr BP. Fossil beetle and pollen assemblages from the peat indicate a fauna and flora very similar to that inhabiting stable substrates within the area today. The implication is that the South Patagonian ice field during the Younger Dryas interval was no larger than it is today and could even have been smaller (Ashworth and Markgraf, 1989).

Biogeographic Considerations

In the montane and island-fragmented landscape of southern Chile, the onset of the last phase of the glaciation is dated at 29 400 yr BP (Denton, et al., 1999). Nothing is known of the

beetle fauna that existed before the final phase of glaciation; however, it is reasonable to assume that it was a forest fauna based on available pollen analyses. Further, it is reasonable to speculate that as the climate cooled, species became regionally extinct. It is assumed that these species survived in more northerly locations and were available for recolonization when the climate warmed between 14 000 and 13 000 yr BP. The fauna that survived glaciation in the moorland habitat of the lake region has no modern analog. It consisted of: (1) species that had dispersed downslope from habitats high in the coastal ranges and the Andes and (2) species that were 'climatic generalists' that could survive the lower temperatures. There is no evidence that cold-adapted species from more southerly latitudes migrated to the lake region.

The absence of evidence for latitudinal movement of beetle taxa in response to climate change during the last glaciation makes southern South America very different than either Europe or North America where species were displaced more than 1000 km from their existing distributions (Ashworth, 2001). The prevailing hypothesis is that the biota south of Chiloé was completely extirpated during the last glaciation and consequently would not have been available to colonize more northerly regions. The hypothesis has serious flaws (see below), but even if pockets of biota did survive to the south, northward dispersal would have been blocked by barriers imposed by marine inlets and large glaciers.

Reconstructions of ice cover for southern South America during the Last Glacial Maximum portray an ice sheet that was continuous from latitude 43° S in the lake region to 56° S in Tierra del Fuego (Hollin and Schilling, 1981) (Figure 1). At the northern end, parts of Chiloé, the coastal ranges, and the central valley were ice free. South of Chiloé, however, ice is shown as covering the coastal mountains and extending to the Pacific Ocean. An equilibrium line altitude lowering of 900 m was used by Hubbard et al. (2005) to model the central regions of the Patagonian ice sheet between 45° and 48° S. Their model shows that by 21 000 yr BP ice covered the Taitao Peninsula extending to the coastal shelf, comparable to the Hollin and Schilling (1981) reconstruction. Using climatic forcing modified from the Vostok ice core, their model shows an ice sheet that slowly retreated until 14 500 yr BP, after which it collapsed rapidly reaching its present-day configuration by 11 000 yr BP after briefly stabilizing during the Antarctic Cold Reversal.

The effect of glaciation is considered to have been devastating to the flora and fauna, resulting in the total extirpation of species south of Chiloé. Two pieces of evidence, however, suggest that the extent of glaciation and extirpation of the biota may have been overestimated. The first is that there are several species of large- to moderate-sized flightless beetles in the basal layer of the bog at Puerto Edén with an age of about 13 000 yr BP. The fossils include the ground beetles *Ceroglossus suturalis* F., *Creobius eydouxi* Guérin, *Cascellius gravesii* Curtis, and *C. septentrionalis* Roig-Juñent, and the weevils, *Aegorhinus kuscheli* Elgueta and *Germainiellus rugipennis* (Blanchard). For flightless species to be among the earliest colonizers of the bog implies that they had to have survived glaciation locally, either in the coastal mountains or more probably along the coast. The second piece of evidence supporting survival in local refugia is the high genetic diversity measured in isolated populations of the tree species *Pilgerodendron uvifera* (D. Don) Florin (Premoli

et al., 2002). If these populations were Holocene immigrants derived by long-distance dispersal from northern refugia, then it would be expected that the severity of the genetic bottleneck they have been through would have resulted in the populations having much lower genetic diversity.

The Younger Dryas Conundrum

One of the enduring problems associated with paleoclimatic interpretation in the Chilean lake region is whether the pattern of climatic changes at the end of the last glaciation was identical to that of the North Atlantic region. In particular, the problems focused on the existence of a Younger Dryas equivalent between 11 000 and 10 000 yr BP. Currently, the question involves whether there is a climatic cooling, the Huelmo-Mascardi cold reversal (Hajdas et al., 2003), between 12 400 and 10 000 yr BP. The initial disagreement centered on several interpretations based on pollen studies for a climatic reversal of 5–10 °C precisely correlated with the Younger Dryas (Heusser, 1974). The studies were considered to be strong evidence for the Younger Dryas being a global event. Ashworth and Hoganson (1993), however, argued that there was no evidence for any significant amount of cooling indicated by fossil beetle assemblages after 14 000 yr BP precipitating a disagreement that continues today.

In southern South America, outside of the Chilean lake region, the evidence for climatic cooling coeval with the Younger Dryas is equally problematical. Ariztegui et al. (1997) reported indirect evidence for a Younger Dryas glacial advance on Monte Tronador, based on studies of sediments, diatoms, and pollen from Lago Mascardi. Redating of that event has demonstrated that the proposed cooling includes the Younger Dryas but pre-dates it by 550 yr (Hajdas et al., 2003). Earlier, pollen studies in the region showed that there had been no response of vegetation to climate change between 11 000 and 10 000 yr BP (Markgraf, 1984). In pollen records from the Chonos (44° S) and Taitao peninsulas (46°), the vegetation shows a unidirectional shift from heath to forest, with essentially the modern forest developed by 12 400 yr BP (Bennett et al., 2000; Haberle and Bennett, 2004). No evidence was found for cooling during either the Younger Dryas or the earlier Antarctic Cold Reversal. However, one of the possible explanations for changes in chironomid (midge) fossil assemblages from a lake studied by Bennett et al. (2000) was for climatic cooling during the Younger Dryas (Massaferro and Brooks, 2002). Further south in the Chilean Channels (49° S) combined analyses of fossil beetle assemblages and pollen also showed no evidence of a Younger Dryas climatic cooling (Ashworth et al., 1991). At the Témpano glacier, Ashworth and Markgraf (1989) reported that the North Patagonian ice field was within its present boundaries during the Younger Dryas. In Tierra del Fuego, Heusser and Rabassa (1987) reported a glacial and vegetational response consistent with cooling during the Younger Dryas. From the same region, Markgraf (1993) reported the occurrence of charcoal during the Late Glacial and preferred to interpret the pollen in terms of local environmental instability rather than climatic cooling.

Moreno et al. (1999) reported a climatic cooling of 2–3 °C between 12 200 and 9 800 yr BP in the Chilean lake region based mostly on the occurrence of the pollen of *Podocarpus*

nubigena Lindl., a conifer which occurs in the North Patagonian and Valdivian rain forests. They discussed how the proposed cooling produced only minor changes in forest structure but still considered climate change to be the probable cause rather than disturbance from a nonclimatic cause. Ashworth and Hoganson (1987) were unable to discriminate statistically between the modern beetle communities of the North Patagonian and upper Valdivian rain forest which, in terms of paleoclimatic interpretation, would translate to ± 1 °C. The difference between interpretations based on pollen and those on fossil beetle assemblages is now within ± 1 °C or what many paleoecologists would consider noise within the records and irresolvable between climatic and nonclimatic causes.

The situation now is very different than when disagreements between interpretations were initially stated. Then, the pollen evidence was unequivocally for a climatic cooling of similar magnitude and timing to the Younger Dryas in the North Atlantic. Currently, even proponents for climate change argue that it is subtle and that it begins 500–1 200 yr before the Younger Dryas. Moreno (1997), Moreno et al. (1999), and Hajdas et al. (2003) still consider the cooling to be part of a globally synchronous event but Ashworth and Hoganson (1993), Markgraf (1993), and Bennett et al. (2000) find no evidence to support climatic reversals at the time of the Younger Dryas (11 000–10 000 yr BP) or during the Antarctic Cold Reversal (14 500–12 900 yr BP).

Late Pleistocene of New Zealand

M Marra, University of Waikato, Hamilton, New Zealand

© 2013 Elsevier B.V. All rights reserved.

Introduction

Fossil beetle reconstructions are relatively new in New Zealand (NZ) with the first published work dating only to 2000. Before 2000, terrestrial paleoenvironmental reconstructions relied mainly on pollen records, which defined regional vegetation patterns for the late Quaternary, from which broad climate inferences were drawn. Quantitative estimates for past climate remained less well defined because there is no clear relationship between temperature and vegetation. Hence, there was a need for additional proxies and particularly for proxies capable of quantifiable paleoclimate reconstruction.

To date, Quaternary beetle assemblages have been recorded from 14 NZ sites (Table 1; Figure 1) ranging in age from 1.3 Ma to late Holocene. This literature includes examining the persistence of beetle species in NZ since the early-mid-Quaternary, the development of a beetle-based climate estimation model, and its application to sites dating from the last glaciation. Paleoecological and biogeographical reconstructions have been made for each site, detailing ecosystems at a local scale and at community and species levels. The following is a review of this literature, prefaced by a summary of present knowledge of the modern beetle fauna and a brief description of the NZ physical environment, identifying factors that affect beetle distribution.

Reference to the Last Glacial Maximum (LGM) follows the definition of Newnham et al. (2007) for an extended Last Glacial Maximum (eLGM) in NZ, 29–19 kcal years BP, which is longer and earlier than the LGM *sensu stricto*.

Background

Modern Fauna

Knowledge of the modern fauna underpins both fossil identification and the ecological controls on distribution that are the basis for paleoclimate reconstruction. The NZ beetle fauna is relatively rich: approximately 5223 native and 356 introduced species have been described, comprising approximately 1100 genera in 82 families (Klimaszewski and Watt, 1997). The actual number of species is unknown but is certain to be significantly higher. The Lynfield survey (Kuschel, 1990), regarded as the most comprehensive survey so far in NZ, identified approximately 1000 species. As this is thought to be about 8% of the total NZ beetle fauna, it suggests the total number is around 10000–10500 species (Klimaszewski and Watt, 1997). Consequently, the 5223 species held in NZ collections represent about half the total NZ beetle fauna but several groups need revision. Endemism is high at most levels, with one endemic family, several endemic subfamilies, high but unquantified endemism of genera and about 90% species endemism. A summary of the dominant families and the number of described species in each of these families is listed in Table 2.

NZ Setting

NZ geography imposes many barriers to the dispersal of insects and the tracking of ecosystems across the landscape in response to climate change. It is an island archipelago focussed on two main islands (North Island, South Island), and has a land area of ~270 550 km². The South Island is dominated by an axial mountain range, the Southern Alps, extending about 500 km along the western side of the island, with peaks reaching over 3000 m. During the eLGM the Southern Alps developed a piedmont icecap that extended the length of the range. Glaciers advanced to the south-western coast of the South Island, while to the east they extended beyond the range fronts onto inland basins and coastal outwash fans. A barrier to biotic dispersal during interglacials is the separation of the North and South Islands by the 32 km-wide Cook Strait. However, during glaciations when sea level was lower, a land bridge existed.

Quaternary Stasis in NZ Beetles

Early and Mid-Pleistocene Beetle Assemblages

Background

Quaternary stasis is the foundation of fossil beetle research because if the fossil specimens represent extant species, their biology and habitat requirements can be observed from their modern counterparts. It is thought that this morphological stasis is a result of Milankovich oscillations where glacial–interglacial climate change continually changed directions of selection pressures and speciation only occasionally occurred through isolation (Bennett, 2004). This is referred to by Coope (2004) as ‘stirring of the gene pool.’ At least this is the case in continental locations where there was high amplitude of climate change and where species had very good dispersal opportunities. NZ provided the opportunity to test this theory of stasis in an island archipelago situation where Quaternary climate fluctuations were relatively subdued and where dispersal options were very limited.

The early-mid-Pleistocene fossils were obtained from a series of coastal outcrops containing ancient forests each buried by volcanic deposits (Figure 2). The stratigraphies and tephra chronologies are described (Alloway et al., 2004) and sites range in age from 1.3 My to 170 000 years old. They are all located in the Auckland Region (Figure 1). This location was ideal to test Quaternary stasis in NZ beetles because the area remained forested throughout glacial cycles and the temperature change between glacial and interglacial conditions was only about 4–5 °C (Sandiford et al., 2003). This location was also ideal because the modern fauna is very well understood and documented (Kuschel, 1990), providing the background comparisons for fossil assemblages for the early-mid-Quaternary assemblages. The investigation was an important step for fossil beetle research in NZ because there is also some evidence for extinctions in some locations (Marra and Leschen, 2004).

Table 1 Summary of the New Zealand fossil beetle sites

Site location	Age of site	Number of fossil taxa	Reference
Awatere Valley	Mid-late MIS 1	80	Marra and Leschen (2004) and Marra et al. (2004)
Awatere Valley	MIS 2	26	Marra and Leschen (2004) and Marra et al. (2004)
Howard Valley	MIS 3–2	54	Marra and Thackray (2010)
Rakaia Valley	MIS 2	29	Marra et al. (2006a)
Waitotara Valley	Late MIS 3	29	Marra et al. (2009)
Kaipara Harbor	Early MIS 3	14	Marra (unpublished data)
Westport	MIS 3–2	76	Burge and Shulmeister (2007a)
Westport	MIS 5–4	42	Burge and Shulmeister (2007b)
Palliser Bay	Last Interglacial	64	Marra (2003a)
Banks Peninsula	Late MIS 6	19	Marra (2003b)

	Total	573	

**Figure 1** Map of New Zealand showing location of research sites mentioned in the text.

The fossil evidence

The fossil beetles from the early–mid-Pleistocene all represent extant species found in the modern regional fauna. They indicate that stasis was the dominant response of NZ beetles during the Quaternary. For example, fossils from the Waiuku Inlet site in the Auckland Region, aged about 1.3 Ma, indicate a coastal swamp forest and include species such as *Cafius algophilus* (Staphylinidae) and *Pericoptus* (either *P. stupidus* or *P. frontalis* (Scarabaeidae)) which are found today in sandy coastal habitats. In addition, three weevil species were

Table 2 List of eight dominant families of beetles in New Zealand and the number of described species in each family (Klimaszewski and Watt, 1997)

Family in order of dominance	Number of described NZ species
Curculionidae (incl. Scolytidae)	1542
Staphylinidae (incl. Pselaphidae)	1021
Carabidae	445
Scydmaenidae	202
Colydiidae	196
Cerambycidae	188
Chrysomelidae	153
Scarabaeidae	144

found: *Microcryptorhynchus perpusillus* (Curculionidae) that lives in the dead branches of trees, *Stenotrupis debilis* (Curculionidae) that lives in tree ferns in swamps, and *Dysnocryptus inflatus* (Anthribidae) that inhabits and feeds on grasses (Marra and Leschen, 2011).

The best example of stasis is from a fossil assemblage aged about 170 000 years, also located in the Auckland Region, which also shows stasis at the community level. This assemblage is from a paleo-forest that was instantaneously buried by an explosive phreatomagmatic eruption (Marra et al., 2006b). Ninety-eight fossil beetle taxa belonging to 28 families were identified, all of which belong to the modern fauna. Fossils were very well preserved and include species such as *Inosomus rufopiceus* (Curculionidae; Figure 3(a)) which inhabits *Agathis australis* (Araucariaceae) and *Dacrydium cupressinum* (Podocarpaceae), and *Heterotyles argentatus* (Curculionidae; Figure 3(b)), a species that inhabits various podocarp trees. The assemblage indicates that the same fauna remained in place or reassembled in the same place across two glacial cycles.

Despite this faunal stability in northern NZ, extinction rates in other locations in NZ may have been higher than in Holarctic locations. Of the ~570 NZ fossil taxa thus far identified (Table 1), three are possible extinctions. These fossils are distinctive and well preserved, but given the number of undescribed species in the modern fauna, it is difficult to say

Figure 2 Outcrops of ancient forests that are buried by volcanic ash deposits that provided the early–mid-Pleistocene fossil beetles: (a) Renton Rd (ca. 170 ka BP); (b) Takanini (0.55 My BP); (c) Point England (ca. 1 My BP); and (d) Waiuku Inlet (1.3 My BP).

Figure 3 Examples of fossil beetles from New Zealand: (a) *Inosomus rufopiceus* (Curculionidae); (b) *Heterotyles argentatus* (Curculionidae); (c) *Ectopsis ferrugalis* (Curculionidae); and (d) *Platypus caviceps* (Curculionidae).

Figure 4 Possible extinctions and local extinction. (a) Prothorax of an unknown species/genus of Limnichidae. (b) Elytron (wingcase) of an unknown species of Cryptorhynchini (Curculionidae). (c) Head, prothorax, and elytra of an unknown species, possibly Latridiidae. (d) Illustration of *Microbrontes lineatus* (Laemophloeidae) and the fossil prothorax and elytron of this species. whether the unidentified fossils belong to extinct species or represent extant taxa that have yet to be collected. One of these is a fossil prothorax from a last Interglacial assemblage that is clearly in the family Limnichidae. The prothorax has a distinctive oblique ridge cutting across each posterior pronotal angle (Figure 4(a)), a feature that is not found on any of the known modern Limnichidae in NZ or Australia. Similarly, four distinctively ornamented weevil elytra (Figure 4(b)) from a marine isotope stage (MIS) 6 site in the eastern South Island are also unknown in the modern fauna.

The third possible extinction is a fossil specimen in the family Latridiidae (Figure 4(c)). It is abundant as a fossil in glacial assemblages and is probably a subalpine species. Although all the major fossil sclerites have been collected, providing good detail for its identification, it has no known modern equivalent.

Extinctions of NZ beetles are well documented for the time since the arrival of predators within the past 2000 years and human settlement ~750 years ago, and the subsequent destruction of forest and shrubland habitats. For example, the large weevil *Ectopsis ferrugalis* (Curculionidae; Figure 3(c)) occurs as fossils in South Island assemblages but it is not found today in the South Island. Its recent absence has been

attributed to introduced predators (Kuschel and Worthy, 1996). This species is important as a fossil because it has a specific host tree and its larvae have specific tree-size burrowing requirements, which not only identify the presence of the host tree, but document its size as well. In some cases, the fossil record is the only evidence of some taxa. For example, a large (24.5 mm) extinct beetle species in the family Ulodidae, found in cave deposits, has been described solely from fossil specimens (Leschen and Rhode, 2002). Its extinction is also attributed to introduced predators.

Prior to human arrival, the fossil data from northern NZ indicate stability in beetle communities over much of the Quaternary. However, the stability of these northern regional assemblages is not reflected in assemblages for the remainder of NZ where, during ice ages, the landscape was dominated by glaciation and vegetation changes were severe. Fossil data from central and southern NZ show that very different communities occurred in these locations in response to changes in climate and vegetation. A very good example is *Microbrontes lineatus* (Laemophloeidae; Figure 4(d)). This species is very rare in modern collections, yet it occurs as a fossil in two locations outside of its modern distribution, which may indicate it may have been more abundant in the past.

Late Pleistocene Beetle Distributions

Changing Distributions

The penultimate glaciation (MIS 6)

The modern beetle fauna of Banks Peninsula (Figure 1) is well known from several published natural histories and inventories (e.g., Johns, 1986). These inventories provide a basis for comparison with a fossil assemblage from Gebbies Valley, Banks Peninsula.

Nineteen beetle fossils extracted from core material are reported in Marra (2003b). The fossil assemblage comprised montane forest taxa in a coastal setting. Based on the modern distributions and upper altitudinal limits of the fossil fauna, Marra (2003b) interpreted the climate as interstadial rather than pleniglacial, and by using a simple environmental lapse rate (0.55 ± 0.05 °C/100 m), she estimated the lowering of the montane zone by ~450 m, from its present elevation down to sea level. This equates to a maximum temperature depression of around 2–3 °C.

Originally, the site was described from pollen evidence as a back barrier, freshwater setting (Shulmeister et al., 1999; Soons et al., 2002). However, the beetle fossils indicate the paleoenvironment was estuarine (Marra, 2003b). The pollen-based description of the surrounding vegetation is of low-forest shrubs (Soons et al., 2002). The fossil beetle *Pachyrinus metallicus* (Belidae), that is host specific to *Podocarpus totara* and *Podocarpus hallii* (Podocarpaceae) provided confirmation of this forest and identified the forest type. Both *P. totara* and *P. hallii* grow on Banks Peninsula but *P. hallii* dominates the higher elevations, so it was probably this species that occupied the lowland site during the cooler MIS 6, as part of the low forest described from the pollen spectra.

The MIS 6 fossil fauna is very different from the modern Banks Peninsula fauna. Of the nineteen beetle species identified, only three weevils (*P. metallicus*, *Eucossonus setiger*,

Cecyropa modesta) are found in the modern Banks Peninsula fauna, although undetermined carabids and species of *Nestrius* and *Bledius* could also be present. Species of *Epichorius* (Byrrhidae) *Spinditeles* (Anobiidae) *Mandalotus*, *Baeosomus*, *Microcryptorhynchus*, or *Scelodolichus* (Curculionidae) in the fossil assemblage are not part of the modern Banks Peninsula fauna. The different faunal composition of MIS 6 fauna is a result of the montane environmental conditions at the site at that time.

The last interglaciation (MIS 5)

The fossil beetle fauna from Palliser Bay on the southern coast of the North Island (Figure 1) (Marra, 2003a) is markedly different from the modern assemblage. The site dates from the last interglaciation, MIS 5. Two fossil beetle assemblages totalling 63 taxa were identified from two organic silt beds occurring in a sequence of fluvial and lacustrine sediments. Both assemblages are similar in that they indicate ecological successions from lake margins to forest but they comprise different taxa. Of the two fossiliferous layers, the lower contained beetles that are found today some 600–700 km north of the study site (Figure 5). This fauna represents a significant southward expansion of northern species compared to modern distributions, despite the physical barrier of the central North Island volcanic plateau. This is a minimum southward dispersal because Cook Strait would have impeded further movement to the south.

Pre-eLGM (late MIS 3)

Fossil beetles from a last glacial landslide-generated lake-forest sequence aged 33 480–34 410 cal years BP (late MIS 3) were identified from the Waitotara Valley (Marra et al., 2009). Information on ancient ecosystems from this site is important because it is located in a region that is characterized by low endemism, low diversity, and disjunctive distributions. The region is described as an ecological gap, and referred to as the Manawatu Gap that is located within a wider ecological gap, the Northern Gap. Many taxa that are otherwise widespread in NZ are absent from this gap. There is much debate about the cause and timing of the Northern Gap. One theory is that it is a result of long term landform evolution dating back to the Oligocene; another theory is that the Gap in distributions is a result of the last glaciation. Therefore, a fossil beetle site from early MIS 3 within the Gap provided an excellent opportunity to examine the antiquity of the Gap.

The Waitotara Valley is characterized by numerous large-scale deep-seated landslides, some of sufficient magnitude to block rivers and form lakes. The fossils were obtained from one of these lakes where the stratigraphy records a lake-forest sequence. Twenty-nine fossil beetle taxa were identified and include such species as *Platypus caviceps* (Curculionidae; Figure 3(d)), which is a timber-boring weevil that inhabits stressed or freshly felled *Nothofagus* (Nothofagaceae) trees. The beetles tunnel into the wood and cultivate the fungi on which they feed (May, 1993).

Of major biogeographical interest is that none of the fossil beetle species are present in the modern regional fauna and many taxa such as *P. caviceps*, *Alema paradoxa*, *Rhyzobius consors* (Coccinellidae), *Syrphetodes ater* (Ulodidae), *Cyclaxyra impressa* (Phalacridae), and species of *Grynoma* (Trogossitidae) and

Figure 5 The modern-day distribution of species as they relate to the fossil site at Palliser Bay. Adapted from Marra MJ (2003) A last interglacial beetle fauna from New Zealand. *Quaternary Research* 59: 122–131.

Pycnomerus (Zopheridae) are now absent from part or all of the lower North Island. These results suggest that the modern biogeographical pattern stems from the last glaciation. There is no obvious ecological or habitat reason for these taxa to be absent in the modern fauna. **Figure 6** illustrates the Northern Gap and the modern distribution of the late MIS 3 fossil species.

eLGM (MIS 2)

Fossil beetle assemblages from the eLGM at Nina Stream in the Awatere Valley (**Figure 1**) in the north-eastern South Island have been reported in **Marra and Leschen (2004)**. The Awatere Valley flows northeast along the northern side of the Inland Kaikoura Range (2880 m). At the site, the Awatere fault transects the stream. This is one of the series of active faults that continue the NZ plate boundary into the North Island.

Movement on the fault impedes stream drainage, which led to the accumulation of a sequence of fan gravels intersected by organic silts. Radiocarbon ages for organic beds at the base of the section are 25 550–23 950 and 24 650–22 050 cal years BP.

The fossil fauna includes subalpine beetles from habitats that include stream side, tussocks, and shrubs. The fauna includes the ground beetles (Carabidae), *Notagonum feredayi* and *Bembidion hokitikense* which today are found near water in tussock grasslands. Other subalpine species include *Peristoreus fusconotatus* (Curculionidae) that lives on *Olearia* (a genus of tree daisies), and a species of *Lyperopais* (Curculionidae) that so far has only been collected above treeline. Both *Acritelater reversus* (Elateridae) and *Aleochara hammondi* (Staphylinidae) also inhabit subalpine tussock grasslands. The fauna suggests a downward shift in the regional vegetation zones of several

Figure 6 The modern distribution of fossil taxa from the Waitotara Valley site showing the modern disjunctive distributions in the Northern Gap and particularly within the Manawatu area. hundred meters, presumably in response to the cold climate conditions (see climate reconstruction given below).

Quantifying Past Climates

Method for Climate Quantification

Method development

A maximum likelihood envelope (MLE) method has been developed (Marra et al., 2004) that is suitable for quantifying past climates from beetle fossils in NZ. MLE was developed to deal with problems associated with the incomplete knowledge of the NZ fauna. Incomplete knowledge limits robust climatic reconstruction because if the observed distribution of species is poorly known, the actual distribution of the ecological tolerances may be underestimated.

The MLE method is based on the premise that beetle distributions are climate driven and that the distribution of each taxon is controlled by finite physiological requirements. It therefore uses a sine distribution model rather than a Gaussian distribution model because a Gaussian model does not

Figure 7 Maximum likelihood (ML) best-high and best-low endpoints attached to a sine distribution model, effectively increasing the climate range of a species.

prescribe absolute limits to distributions needed for the presence–absence approach intrinsic to beetle climate modeling (e.g., mutual climate range – MCR; Atkinson et al., 1987). Maximum likelihood (ML) best-high and best-low values are determined and fitted to sine distributions to allow for the uncertainty that the samples are realistic representations of the actual climatic distributions. Figure 7 illustrates how the estimated ML endpoints effectively increase the distribution of a taxon. The endpoints define a 95% confidence distribution.

Climate variables for reconstruction

The climate reconstructions are based on mean February and mean minimum July temperatures. Although MCR is based on summer temperature and seasonality, seasonality is much more subdued in NZ than in continental locations, so it is unlikely that this is a major climatic consideration. Anecdotal evidence suggests that length of summer and extreme winter temperatures may drive beetle distributions and hence, mean February and minimum July temperatures.

These climate variables were tested (Marra et al., 2004) by pooling the distribution data points of all the species. Each datum (x_i) was transformed to $(x_i - a)/(b - a)$ to give each species' actual distribution and relative position on a standard range (0,1) of all the data points (all the distribution points of all the species; Figure 8).

The test showed that the sine model fitted the July minimum temperature rather well, but the February mean temperature pooled data were significantly positively skewed. As the same skewness is not apparent in the July minimum temperature data as expected, it suggests that, aside from temperature, some other climate variable was affecting beetles significantly in summer but not in winter, and this may be related to moisture.

eLGM Climate Reconstruction

Lyndon Stream

Using MLE, the temperature for an interval during the eLGM was estimated from fossil beetles from the Lyndon Stream (Marra et al., 2006a). Lyndon Stream is located in the eastern foothills of the Southern Alps (alt. ~700 m; Figure 1) proximal

Figure 8 Graphs showing the fit of sine models to the climate variables for mean February temperature (a) and mean July minimum temperature (b). Pooled mean February data and best-fitting sine model and bi-sine model (a) and pooled mean July minimum temperature data and two sine models; sine and sine-tapered boxcar (b). Adapted from Marra MJ, Smith EGC, Shulmeister J, and Leschen R (2004) Late Quaternary climate change in the Awatere Valley, South Island, New Zealand using a sine model with a maximum likelihood envelope on fossil beetle data. *Quaternary Science Reviews* 23: 1637–1650.

to, and a tributary of the Rakaia river valley, which contained a major glacier during the eLGM. The site comprises lake beds bounded by eLGM proximal outwash, confining the lake within the eLGM chron (Figure 9). The site was first examined by Soons and Burrows (1978) who dated the paleolake to between 24 840–26 100 cal years BP (base of the section) and 21 980–23 280 cal years BP (top of the section). Using pollen and plant macrofossils, they described an environment during the eLGM that was nearly identical to modern conditions.

Nine fossil beetle taxa were used to reconstruct mean February (summer) and mean minimum temperatures for July (the coldest month; Marra et al., 2006a).

The February temperature reconstruction is illustrated in Figure 10. The broken line is the modern temperature at the site, and horizontal bars are the temperature ranges for the

Figure 9 The Lyndon Stream site lake beds bounded by extended Last Glacial Maximum (eLGM) proximal outwash.

taxa. The shadings at the end of each bar are the ML best-high and best-low statistical endpoints. The envelopes (yellow or shaded) are the mutual temperature overlaps of all the taxa, which are defined at the lower limit by the species with the highest minimum, and the upper limit by species with the lowest maximum. The yellow shows the overlap of the known temperature ranges, whereas the shaded envelope is the MLE estimate that has statistically extended the known ranges. The estimates indicate that the mean temperature at the site at eLGM was between 0.5 °C warmer and 1.9 °C cooler in February than at the present day. The modeled mean minimum winter temperature was similarly close to present values, being between 1 °C warmer and 2.2 °C cooler than present day.

Even at the cooler extremes of these modeled estimates, the climate during the eLGM appears to have been milder than that of the traditional view, for which the temperature depression has been estimated at 4–7 °C (e.g., Porter, 1975; Soons, 1979). However, the predictions from beetle environmental requirements fit remarkably well with the reconstructions from plant macrofossils and are consistent with new evidence of relatively mild conditions (Hormes et al., 2003) during at least some periods within the eLGM in NZ.

Awatere Valley

In contrast, the MLE climate reconstruction for the Awatere Valley, ~300 km to the north (Marra et al., 2004), shows a very much cooler climate during the same time (24 650–22 050 and 25 550–23 950 cal years BP) during eLGM. At this site, summer (February) mean temperature was ~3.5–4 °C cooler, and July (winter) mean daily minimum temperature was ~4–5 °C cooler than present day temperatures. The ML estimates broadened the reconstructed temperature ranges to 2.5–5 °C cooler for February temperatures and 3.5–6.0 °C cooler for mean minimum daily temperature of the coldest month (July). These estimates are more consistent with the traditional cooler eLGM model of 4–7 °C cooler.

The conflict between sites of apparently similar age needs to be resolved. It is most likely to be a result of poorly constrained ages. Tighter age control may reveal that these sites are close but not identical in age, and that the different environmental estimates reflect rapid climate change from cold glacial to warm interstadial such as described above at the Lyndon

Figure 10 Application of maximum likelihood envelope to reconstruct the mean February temperature for the eLGM at Lyndon Stream showing the difference between the present-day temperature at the site to the estimated temperature at the eLGM. Adapted from Marra MJ, Shulmeister J, and Smith E (2006) Last glacial maximum beetle fauna, Lyndon Stream, Rakaia River Valley, South Island, New Zealand. *Quaternary Science Reviews* 25: 1841–1849.

Stream site. Another possibility is that the Lyndon Stream site plots are warmer because they are sheltered from cold southerly and easterly winds.

Reconstructions of rates of climate change have not yet been attempted. The ability to determine rates of climate change and to identify short-term climatic oscillations is the real strength of fossil beetle analyses and these should be investigated. There is also no literature on the Postglacial warming, an interval of rapid climate change about which there are many conflicting proxy reconstructions.

Forest Refugia in NZ During the eLGM

Fossil Beetle Evidence for Forest Refugia

Awatere Valley

Late Pleistocene beetle research has highlighted the importance of scale in reconstructions (e.g., Marra and Leschen, 2004). It is evident that pollen provides regional-scaled vegetation information, but the beetles provide local-scale insights. For example, pollen data indicate that the vegetation in the eastern South Island was predominantly grassland from 26 000 to 12 000 years BP (Moar, 1980). Low values of tree pollen indicated that trees were present throughout this period, although the actual source of the pollen remains a mystery. The fossil beetle assemblages from several sites precisely indicate the location of one of these glacial-aged forest patches/refugia. The first and most exciting of these discoveries was that of the forest-dwelling beetles in the Awatere Valley fauna, the most significant of which was the weevil *Hypotagea lewisi* (Curculionidae; Figure 11(a)) which is host-specific on living *Nothofagus* trees, both the larvae and adults feeding on *Nothofagus* parenchyma tissue.

Figure 11 (a) The head capsule of *Hypotagea lewisi* (Curculionidae). (b) Head capsule of *Rhopalomerus tenuirostris* (Curculionidae). Images by B. Rhode of Landcare Research (scale bars = 1 mm).

The fossil of *H. lewisi* pinpoints a stand of *Nothofagus* forest in Marlborough during the eLGM, the first confirmed eastern forest refugium for this time. No *Nothofagus* pollen was found at the site but recent additional (unpublished) data include additional beetle taxa associated with *Nothofagus* plus fossil leaves of *Nothofagus solandri*, both of which confirm the original interpretation of this forest refugium.

The Lyndon Stream

Similarly, although the data are not as conclusive as those from the Awatere Valley, the Lyndon Stream eLGM fossil beetle fauna also contains at least two forest taxa. The pollen and plant macrofossils at the site indicate that the local vegetation at the eLGM consisted of grasses and shrubs. However, the beetles suggest a more diverse ecosystem at that time. The 25 fossil beetle taxa identified from Lyndon Stream represent a

Figure 12 Illustration of new species of *Phyllocharitini* (Chrysomelidae) and the fossil elytra. The illustration is by D. W. Helmore, courtesy of Landcare Research, NZ. Image by B. Rhode of Landcare Research (scale bar = 1 mm).

rich and diverse ecosystem at the paleo-Lyndon lake at some period during the eLGM (Marra et al., 2006a). The beetles are typical of those found in high-country Canterbury lakes, which is consistent with the inferred interstadial climate discussed above, though it must be noted that the modern landscape is partially deforested by human activity. Although most of the fossil beetles are aquatic and riparian taxa, the assemblage also includes the weevil species *Rhopalomerus tenuirostris* (Figure 11(b)). Adults of *R. tenuirostris* feed on pollen, but the larvae inhabit very rotten wood, typically on the forest floor. In addition the fauna included a species of *Phyllocharitini* (Chrysomelidae; Figure 12). This is a newly-discovered taxon that is found in wet forests. Although not conclusive, the presence of these two taxa supports the presence of forest habitat at the site.

Westport

Burge and Shulmeister (2007a) characterized the fossil beetles from the Westport area (Figure 1) from a paleo-dunefield environment that spans 37 000–21 300 cal years BP. The palynology of sediments from the site indicates subalpine shrubland prior to glacial onset (34 000 cal years BP) and widespread grassland with little woody vegetation during the period of maximum glacial cooling. Fossils of forest beetles indicate forest vegetation prior to glacial onset, and a mosaic of closed canopy patches and open tussock grassland during full-glacial conditions.

The Howard Valley

Howard Valley is located in southwest Nelson in the Nelson Lakes district, at the northern end of the Southern Alps (Figure 1), between the Rotoiti and Rotoroa valleys. The area was extensively glaciated at the height of the last glaciation when glaciers flowed from surrounding ranges down the Rotoiti and Rotoroa valleys. The Howard Valley was not

glaciated because its headwaters do not extend into the Southern Alps as they do in the adjacent valleys.

Extensive terraces can be located in the Howard Valley and outcrops reveal stratigraphic sequences of alternating fluvial gravels and organic rich silts dated between ca. 34 000 and ca. 18 500 cal years BP. The paleoecological investigation of three sites along the terraces provided very good evidence for a forest refugium at times during the eLGM. Fifty-four beetle taxa represent seven habitat types: forest, forest or scrub, riparian and aquatic, litter, grass/tussock, marshland, and moss habitats. Fossils are supported by leaves of *Nothofagus menziesii*, which provide evidence of a forest refugium. Tree-line taxa such as *Taenarthrus* sp. 1 (Carabidae) and *Podocarpus* sp. (Podocarpaceae) indicate that the site may represent the upper tree limit for full-glacial time. Fossil forest taxa at this elevated site add to the growing fossil evidence for multiple forest refugia in NZ during the last glaciation and are consistent with the pollen records that have consistently indicated the presence of forest species during the last glaciation (Marra and Thackray, 2010).

Thus, the fossil beetle assemblages from several sites provide information on forest refugia during the eLGM. These results challenge the model of open vegetation at low elevations during glacial periods and a new model has emerged that shows forest persisted in areas previously considered grasslands. Figure 13 shows the altitude of eLGM sites where forest fossil beetles occur. They are illustrated against the modern altitudinal vegetation zones. The altitudes at which eLGM forest occurred are within the expected down slope adjustment (environmental lapse rate of 0.55 ± 0.05 °C/100 m) associated with the eLGM cooling of 4–5 °C estimated for NZ.

In addition, the eLGM forest stands/refugia have similar environmental conditions in that they are all in interior, sheltered valleys. They are also sites where moisture was not limited because at each location the local hydrology was disrupted by a geomorphic factor (such as landslide, fault movement, etc.)

Figure 13 North-south profile of New Zealand showing eLGM forest sites against modern altitudinal vegetation zones. Adapted from Marra MJ and Thackray GD (2010) Glacial forest refugium in Howard Valley, South Island, New Zealand. *Journal of Quaternary Science* 25: 309–310.

that impeded local drainage, allowing lakes and swampy environments to be formed (Marra and Thackray, 2010). The combination of moisture availability and protection from wind appears to have increased the survival of forest species in sheltered inland areas.

Glossary

Dendrophilic Species that live and feed on trees.

Thermophilic Species that live in relatively warm climates.

Xerophilic Species that prefer dry and relatively warm habitats, often on open ground, with or without sparse shrubs and trees.

Xylophages Species that feed on wood.

Late Pleistocene Beetle Records from Northern Asia

Preservation, Abundance, and Collecting Fossil Beetles in the Siberian Arctic

Insect fossils are common in various types of Quaternary deposits in Northern Asia. They are most abundant and well preserved in silt or sandy silt with plant detritus. Two main factors – the predominantly fine-grained composition of sediment matrix and ubiquitous permafrost – allow excellent preservation of the Late Pleistocene (LP) insect fossils in this region (Figures 1 and 2). Massive peat layers in the Arctic usually contain few insect remains, but thin-bedded peat intercalating with silt may contain rich insect faunas. The coarser sediment, such as sand with fine gravel deposited in rapidly running water, usually preserves only the most durable insect remains (Figure 3).

The average abundance of insect fossils in the sediment is not very high (Table 1). This means that in order to obtain a statistically representative sample with a minimum number of 100 individuals, it is necessary to process 50–60 kg of moist sediment with an average content of fossils, and sometimes up to 200 kg of sediment with a poor content of fossils. Taking into account the difficulties and expense of working in remote arctic regions, usually several weeks are spent at one site and 20–30 samples are collected there. The enormous cost of transportation makes it mandatory for one to reduce the weight of samples to be shipped, so samples are screened in the field (Figures 4–5) and after that pick up insects in the laboratory (Figure 6).

The identification of insect fossils in Northern Asia is difficult because of insufficient knowledge of both taxonomy and distribution of modern species. That is why modern insects are always collected during the authors' field season in these remote regions. This only marginally advances the cause of regional beetle taxonomy, however. Many groups are still poorly studied.

Localities of Fossil Beetles in Northern Asia

The first studies of Pleistocene insects in Northern Asia took place in the 1960s (Grushevskiy and Medvedev, 1962). These studies were associated with famous discoveries of complete mammal carcasses in permafrost or rich accumulations of mammoth bones, the so-called 'mammoth cemeteries' (Medvedev and Voronova, 1977). The regular sampling of Quaternary sediments for insect fossils in Northeastern Siberia and their

systematic research was started in the 1970s by Sergey Kiselev (1981). Until 2004 Svetlana Kuzmina continued Kiselev's work in that region, and Evgeny Zinovyev studied Quaternary insects in northwestern Siberia.

More than 30 years of regular paleoentomological research in Northern Asia has resulted in a large number of studied sites and analyzed assemblages, but their distribution over such a vast territory is uneven and discontinuous. For example, Zinoviev (1997) studied about 36 sites in northwestern Siberia, most of them of LP age. However, further east, the huge region between the mouth of the Ob' River and almost to the Lena River Delta is virtually unstudied. From the Lena Delta to Chukotka (Northeastern Siberia), the number of sites is much higher, but they are unevenly distributed (Figure 7). More than 200 LP beetle assemblages have been studied from 44 localities in this region (Table 2). The most important are discussed below.

Geological Background of the LP Beetle Record in Northern Asia

Northern Asia from west to east

While northwestern Siberia and the Taimyr Peninsula were strongly affected by the advances of the Barents-Kara Ice Sheet (Svendsen et al., 2004), no ice sheets existed east of the Taimyr. Only some high mountain ridges received enough moisture to build valley glaciers. Thus, the huge territory of Northern Asia between the Taimyr and Chukotka (i.e., between about 112° and 175° E) has never experienced major glaciations. Instead, this area was a broad arena for permafrost and periglacial processes. At present, the environment of the vast lowlands bordering the East Siberian and Laptev Seas is strongly influenced by the Arctic Ocean, but in the LP these flatlands had a much more continental climate, as they extended much further north during long periods when the shallow continental shelf was above sea level.

What is Yedoma?

The most remarkable and widespread Pleistocene sedimentary unit on these flatlands is ice-rich silt and sandy silt with thick ice wedges (Figure 8). It usually builds the main surface of the lowland (up to 60–100 m above the rivers) or its remaining hills when it is destroyed by thermokarst and erosion. Local people call these hills 'Yedoma,' and geologists used that name for this kind of sediment (Figure 9). The high content of ice in Yedoma sediments (up to 80%; Figures 10 and 11) explains

[†]Deceased.

Figure 1 Fossil scales on the surface of the weevil, *Hypera ornata*, Bykovsky Peninsula, late Pleistocene. The condition of fossil chitin in frozen silts is usually as good as in modern beetles. Even such delicate and fragile elements as scales, hairs, and antennae are sometimes preserved.

Figure 2 Fossil head, pronotum, and leg of a dung beetle *Aphodius* sp., from the Duvanny Yar site, late Pleistocene. Excellent preservation is common for beetle remains recovered from buried ground squirrel nests, where some specimens have been found with legs preserved in their original position.

Figure 3 Fossil head capsules of weevils (above and right) and a predaceous diving beetle (below, left) from a sandy gravel unit, Keremesit River.

another common name for this formation – Ice Complex. Some important features of Yedoma, or Ice Complex, are shown in [Figures 12–14](#).

The same kind of ice-rich silt builds not only thick sequences of high Yedoma, but also lower terraces ([Figure 15](#)). It is also found on the slopes of rock hills and fills the valleys of small creeks in the highlands. In other words, a similar kind of sediment can occur in many different depositional environments. That is why earlier heated debates about the origin of Yedoma silts (fluvial, eolian, eluvial–colluvial, etc.) gradually gave way to the understanding that the ice-rich Yedoma silts are of polygenetic origin. They include sediments of different facies, which appear similar due to the homogeneity of the original material generated by cryogenic weathering during the Pleistocene and due to the activity of permafrost processes that universally affected sedimentation in various environments.

In closer proximity to mountain areas, active denudation yielded mostly coarser sediments, especially sands. These are the so-called Sand Yedoma sections known in various regions of Northeastern Siberia. Usually, but not always, they include much smaller ice wedges ([Figures 16 and 17](#)). A similar situation can occur along large rivers, building sand terraces with scattered ice wedges.

Thus Yedoma is not a facies, but a type of sedimentation reflecting a specific climate and environment, and in this sense the synonym ‘Ice Complex’ seems more correct. Interestingly, similar sedimentation took place in northwestern Siberia, when the Barents-Kara ice sheet retreated north in the Late Weichselian (LW) ([Svendsen et al., 2004](#)). The widest distribution of the Ice Complex sediments and their overall similarity make their stratigraphic characterization difficult.

Other types of sections

Numerous sections of ‘alasses’ – thermokarst depressions formed by the thawing of the Ice Complex – are another widespread element of regional geology. The majority of them were formed at the Pleistocene–Holocene transition, and are composed of reworked Yedoma silt or sand with low ice content ([Figure 18](#)). They may include a lacustrine unit of former thermokarst lakes and are overlain by a more or less thick peat layer, usually of early Holocene age. Earlier thermokarst events are recorded in buried alas units. They have a similar composition, but are overlain by an Ice Complex unit, and so mark periods of regional, or at least local, degradation of permafrost in the past. In several sites where ancient alas sediments underlie the Weichselian Ice Complex, and overlie supposedly middle Pleistocene units, they probably represent the Last Interglacial (Eemian). Only one such case has been documented by direct dating (infrared stimulated luminescence (IRSL), Krest-Yuryakh at Bolshoy Lyakhovsky Island; [Andreev et al., 2004](#)). If a thermokarst lake reappeared several times in one place, then composite sections formed, consisting of a few superimposed alas complexes ([Figure 19](#)).

The LP stratigraphy in Northeastern Siberia

The stratigraphic subdivision of Ice Complex (Yedoma) sequences is not easy because of the high homogeneity of the sediments. It is mostly based on radiocarbon dating, which makes it possible to reliably distinguish the LW units, but problems were encountered with the Middle Weichselian ([Sher and Plakht, 1988](#)). Ice Complex sections are referred to

Table 1 Concentration of insect fossils in the late Pleistocene frozen silts. The Lena Delta, Late Weichselian, Mamontouy Khayata section

<i>Sample No.</i>	<i>Weight of the screened wet sediment (kg)</i>	<i>Number of insect fossils extracted</i>	<i>MNI (minimum number of individuals)</i>	<i>The number of fossils per kilo</i>	<i>The number of insect individuals per kilo</i>	<i>Weight of matrix to be screened to get 100 insect individuals (kg)</i>

MKh99-3a	7	85	43	12.5	6.3	16
Average				6.0	3.1	62

Note: The volume of screened sediments in these samples is small, as they were screened by geologists. However, the weight of samples was measured, and this case can be used to estimate concentration of fossils.

Figure 4 Sediments in the field are screened, using a large hand-made box with 0.5 mm mesh sieve, letting river, lake, or pond water in and out through the sieve only. The screening is aimed at removing most, but not all of the mineral component, so some amount of silt remains in the box, helping preserve the shape of many fossils smaller than 0.5 mm that might otherwise be lost. These specimens usually float on top of the silt and remain in the sample.

the Early Weichselian if they have an infinite ^{14}C age and are overlain by the dated middle to LW sediments. Strictly speaking, such arguments are not fully conclusive. There are Ice Complex sections dated from the late middle Pleistocene (Kaplina et al., 1980a,b), or even earlier. On the other hand,

Figure 5 The screen residues are dried as much as the weather allows, at first openly, later in fabric bags.

the Ice Complex units with 'finite' ^{14}C dates in the range 35–45 ka do not necessarily belong to the Middle Weichselian, as there were many cases when such units turned out to be much older (Sher et al., 2005).

Table 3 summarizes the geological position and the age of the LP sites from which the insect assemblages have been studied.

Peculiar Features of Fossil Beetle Assemblages in Northeastern Asia

General composition

The species composition of the Pleistocene beetle fauna of Northeastern Asia is strange, compared with the other arctic regions:

1. It has higher diversity and abundance of plant-feeding insects, mostly weevils (Curculionidae) and leaf beetles (Chrysomelidae). Even among ground beetles (Carabidae), mostly a predatory family, one of the commonly found species is a plant-feeder *Curtonotus alpinus*.

Figure 6 Quite often, silt sticks to the fossils, or fills the insides of pronota, head capsules, or joined elytra. This limits the effectiveness of the laboratory flotation method. Instead, dry residuals are separated into the size fractions through regular soil sieves, then the insect and other fossils are picked by hand, under binocular microscope for smaller fractions.

2. Fossil assemblages usually include many species that currently live in tundra and forest tundra, but the diversity of some groups, such as litter inhabitants (rove beetles), carion beetles, and fungus beetles, is notably lower than in modern tundra communities. Also, the diversity of water and riparian species in the fossil assemblages is less than today in the Arctic.
3. Along with tundra species, most Pleistocene assemblages show significant numbers of steppe, meadow-steppe, and other xerophilic insects. Especially notable is the abundance of the pill beetle *Morychus viridis*, an inhabitant of cold steppe-like biotopes in Northeastern Siberia today (see [Tables 4, 5 and 6](#)). This species makes up as much as 90% of some LP insect assemblages.
4. Xylophages and other dendrophilic species are very rare in the LP insect assemblages in this region, so no true forest environment can be reconstructed here for any part of the LP.

The above features characterize many LP insect assemblages in Northeastern Asia, which combine species presently inhabiting a variety of different regions and ecosystems. For example, such arctic species as the ground beetle *Pterostichus costatus*, the leaf beetles *Chrysolina tolli* and *Ch. subsulcata*, and the willow weevil *Isochnus arcticus*, are often found in one fossil assemblage with such steppe leaf beetles as *Ch. perforata*, and the weevils *Stephanocleonus eruditus*, *S. fossulatus*, and *S. incertus*, which now live in southern Siberian and Mongolian steppe. On the other hand, these assemblages sometimes include a few species of insects whose current distribution is restricted mostly to the taiga zone, such as the boreal ant species *Camponotus*

Table 2 The distribution of studied insect assemblages of the late Pleistocene age in Northeastern Siberia

Region	Number of studied sections	Number of insect samples with MNI > 30
Lena Delta (1–3)	3	63
Yana-Indigirka Lowland (14,16,17,19,22,24,25)	11	42
New Siberian Islands (4)	4	11
Kolyma Lowland (5–9,13,15, 20,21,23)	16	50
Medvezhyi Islands (26)	2	4
West Chukotka (Chaun) (11,18)	3	16
Ayon Island (10)	4	38
South Chukotka (Main R.) (12)	2	7
Total	45	231

**Figure 8** One of the famous exposures of late Pleistocene icy silts – Vorontsovskiy Yar on the Indigirka River. The top of this bluff, which is about 40 m high, lies about 90 m above the river level.**Figure 9** The Duvanny Yar site, in the lower course of the Kolyma River, is a cut bank exposure of the so-called Omolon-Anyuy Yedoma – the high-eroded surface between the Omolon and Anyuy Rivers – large tributaries of the Kolyma.

herculeanus and *Formica gagatoides*, the weevils *Hylobius piceus* and *Pissodes irroratus*, and others.

Table 4 lists the most common species of LP beetles found in more than 40% of all LP assemblages and, additionally, a few less abundant, but rather indicative species. Figure 20 shows the fossils of some beetle species found in the LP sediments in Northeastern Siberia.

**Figure 10** Mamontovyy Khayata Cliff, Bykovsky Peninsula, eastern side of the Lena R. Delta. Extensive ice bodies such as this, which in earlier times were interpreted as buried glaciers, in fact represent polygonal systems of syngenetic (growing simultaneously with continued sedimentation) ice wedges.**Figure 11** The ground pillars between the ice wedges also contain lots of ice, but as small layers and microscopic lenses segregated when the silt was freezing.

Non-analog assemblages. What is tundra-steppe?

The fossil insect assemblages of the kind discussed above have no modern analog. They resemble non-analog Pleistocene mammal communities, in which, for example, saiga antelope, a modern inhabitant of dry steppe and semidesert, existed

Figure 12 One of the typical features of Yedoma silts is the abundance of very thin plant roots, most likely belonging to grasses. They occur *in situ* and usually form complicated branching systems, permeating frozen silt.

Figure 13 Some frozen silt layers include woody roots of small shrubs.

together with arctic fox and musk ox. It has been shown that such assemblages are not a random mixture of fossils, but a natural combination of species related to a peculiar type of Pleistocene environment (Sher, 1988, 1990; Vangengeim, 1977). In Russia, this environment and associated plant and animal communities are traditionally called ‘tundra-steppe’ after Tugarinov (1929). In Europe, tundra-steppe communities were related mostly to the periglacial zone south of the ice sheets, but in Siberia, under a more continental climate, they were distributed much more widely and existed more permanently (Vangengeim and Ravsky, 1965). Kiselyov (1981) has shown that insect assemblages of the tundra-steppe type were very common in Northeastern Siberia during the Pleistocene. Moreover, he demonstrated that such insect communities developed in Siberia as early as the late Pliocene. Steppe elements

Figure 14 The Yedoma silts are very rich in various kinds of fossils – plants, freshwater shells, and insects. The most famous remains are the large number of mammal bones and complete or partial frozen carcasses of Pleistocene mammals.

Figure 15 The same kind of ice-rich silt builds not only thick sequences of high Yedoma, but also terrace-like bodies of lower elevation (Low Yedoma, 15–25 m above the river), more clearly positioned in river valleys (Omolon River, Kolyma River basin).

were especially abundant in tundra faunas during relatively cold (glacial) periods, but they survived even during warmer (interglacial) times (Kiselyov, 1981, 1994). The significant destruction of tundra-steppe communities occurred only at the Pleistocene–Holocene boundary, when the dry Pleistocene grassland mostly disappeared, giving way to wet tundra and bogs. This brought about the extinction of the most remarkable large mammalian herbivores, such as mammoth and woolly

Figure 16 Impressive sand sequences up to 60 m high are usually exposed where large rivers run in low mountain areas. The best-known examples are Sychnoy Yar on the Indigirka River and in the city of Verkhoyansk area (Yana and Adycha River basins). A coarser sediment (sands) limited the scale of frost cracks, and the ice wedges in these fluvial sequences are much smaller than in classical Yedoma. They are restricted to the lenses of silty sand (floodplain and ox-bow deposits).

Figure 17 The Ice Bluff section, Main River, southern Chukotka. Sand sections such as this, with a higher content of silt, allowed the continuous growth of ice wedges.

rhino, and the dramatic shrinkage of ranges of others, including horses, bison, and saiga antelope. However, the plant communities of the tundra-steppe type persisted in relatively small relic habitats (Yurtsev, 1981). The ranges of steppe insects also shrank, but many of them survived in relic steppe habitats. Such habitats are widespread in the inner mountains of Northeastern Siberia that have an extremely continental climate. Many thermophilic steppe species found refugia there on south-facing slopes (Berman et al., 2001). Less thermophilic steppe beetles were able to survive in the warmest localities in the Arctic, these habitats being especially abundant on Wrangel Island (Berman, 1986; Khruleva, 2004). The persistence of these beetle species – relics of the Pleistocene tundra-steppe – is one of

Figure 18 In the thermokarst (alas) sections, the Ice Complex sediments have thawed through, that is, reworked in place. As a result, the ice content is much lower here, as former ice wedges have been replaced by ice-wedge casts, or pseudomorphs.

Figure 19 One such reworked section, Molotkovsky Kamen' at the Malyy Anyuy River, had been selected as the regional type of Middle Weichselian Interstadial (Molotkov Horizon) with alternating warmings and coolings. Subsequent redating of the buried peat layers in this section, however, showed much earlier ^{14}C dates, so the age of the Molotkov Horizon should be revised (Sher et al., 2005).

the most remarkable features of the present insect fauna of Northeastern Siberia.

Comparison of Insect Assemblages of Different Ages Using Ecological Grouping

The high frequency of occurrence of a restricted number of species in fossil assemblages (Table 4), and the permanent presence of insects associated with tundra, steppe, and other xerophilic habitats makes the species composition of various assemblages from the Pleistocene of Northeastern Siberia rather monotonous. They differ from each other mostly in the relative abundance of fossils of certain taxa. That is why Kiselyov (Kiselyov, 1981; Sher et al., 1979) used a quantitative approach to trace faunal and environmental changes through time. He classified all species into a number of ecological groups according to their preferred modern habitat, and then he counted the total number of individuals belonging to all species in each group. It was much easier to compare

Table 3 Geological position and the age of the late Pleistocene sites in Northeastern Siberia, from which the insect assemblages have been studied

<i>The section type</i>	<i>Sediment</i>	<i>Geocryology</i>	<i>Sections and map no., figure</i>	<i>Age range</i>	<i>Reference</i>
High Yedoma section (40–60 m and more above the river or sea level)	Mostly silt with sandy silt	One penetrating system of large ice wedges	Mamontovyy Khayata (Figure 7 , No. 3; Figure 10)	EW (?)–MW-LW (>50–12 ka)	Sher et al. (2005)
			Duvanny Yar (Figure 7 , No. 8; Figure 9)	Mostly EW (?)–MW?. Probably LW at the top (>50–18 ka)	Sher and Plakht (1988)
		Multiple (2–3) overlying systems of ice wedges	Khomus-Yuryakh, Loc. 83 (Figure 7 , No. 21)	Late middle Pleistocene	Sher (unpublished)
High Sand section (>30, up to 60 m and more above the river or sea level)	Sand, silty sand	Relatively small ice wedges are restricted to more silty lenses	Sypnoy Yar (Figure 7 , No. 22; Figure 16)	LP undivided (>45 000 years BP in the lower third of the section)	Kaplina (1981)
			Utatgyr Suite, Ayon Island (Figure 7 , No. 10)	LP undivided	Svitoch (1980) and Kiselyov (1994)
		One penetrating system of large ice wedges	Ledovyy Obryv (Ice Bluff) (Figure 7 , No. 12; Figure 17)	MW-LW (42–15 000)	Anderson, et al. (2002) and Sher (unpublished)
Topping Yedoma – Ice Complex up to 20–25 m thick on the top of composite sections	Mostly silt with sandy silt	One penetrating system of large ice wedges	Buor-Khaya (Figure 7 , No. 2)	EW-LW (>50–17 ka)	Schirrmeister et al. (2003)
			Nagym (Figure 7 , No. 1)	MW ? (44–45 ka)	Schirrmeister et al. (2003)
			Zimovye R. Mouth, Bol. Lyakhovsky Island (Figure 7 , No. 4)	EW-MW (100–28 ka)	Schirrmeister et al. (2004)
			Yakutskoe Lake (Figure 7 , No. 23)	LW?	Kiselyov (1994)
			Khroma, Alazeya, Chukochya, Krestovka (Figure 7 , No. 17, 5, 6, 20)	EW-MW? (Alazeya, the date of 38 ka in the lower part of the unit)	Kaplina et al. (1981)
			Achchagyy-Allaikha (Figure 7 , No. 24)	Late middle Pleistocene	Kaplina et al. (1980a,b)
			Oyagosskiy Yar (Figure 7 , No. 19)	Late middle Pleistocene–LW	Nikolsky and Basilyan (2003)
			Omolon-I (Figure 7 , No. 13; Figure 15)	LW (24–15 ka)	Sher (unpublished)
Low Yedoma terraces (20–30 m high above the river level)	Mostly silt with sandy silt	One penetrating system of large ice wedges	Krasivoye Bluff (Figure 7 , No. 15)	LW (18 700 years BP)	Kiselyov (1994)
			Shamanovo (Figure 7 , No. 16)	MW-LW (33 ka and younger)	Kaplina et al. (1980a,b)
			Alyoshkina Zaimka (Figure 7 , No. 7)	LW (17.2–13.2 ka) from >28 ka to early Holocene at the top	Sher et al., 1979; Alfimov et al. (2003); Pitul'ko et al., 2007
Low Sand terraces (20–25 m high above the river level)	Sand, silty sand	Relatively small ice wedges are restricted to more silty lenses.	Yana archaeological site		
Multilayer alasses	Silt, peat	Ice-wedge pseudomorphs	Primorskiy, coast near Rauchua R. mouth (Figure 7 , No. 18)	>28 000 years BP in the lower part of the sequence, 24 800 years BP in the middle part, 10.4 ka at the top	Kiselyov (1994)
Buried alass complexes	Silt, peat	Ice-wedge pseudomorphs	Khroma, Kyl-Bastakh Layers (Figure 7 , No. 17)	LI? (overiles mid-Pleistocene Khroma	Kaplina et al. (1983)

assemblages from different horizons or even sites by the percentage of ecological groups. The authors use the same method with minor variations (Table 5).

For large sections with many insect samples, percentage diagrams are used for better presentation. Recently, the authors suggested the establishment of Insect Faunal Zones (IFZs) in such sections, based on the ecological structure of assemblages. This zonation scheme is similar in some ways to pollen zones (Sher et al., 2005). In Figure 21, one can see how the composition of insect assemblages changed in the Lena Delta during the last 50 ka (this sequence will be considered in more detail below).

The LP Beetle Faunas of Certain Periods and Areas

Below the most important LP beetle assemblages are described, starting with the youngest because they are the most reliably dated (Table 3).

LW insect assemblages

The fossil insect assemblages dated from about 24 to 12 ka were first studied in the Kolyma Lowland, which later proved to be almost the center of continentality and formation of

steppe habitats in the whole of Northern Asia during the Pleistocene. The most interesting of these sites is Alyoshkina Zaimka on the lower course of the Kolyma River (Figure 7, no. 7; Table 3). This site yielded four rich insect faunas within the range of 17–13 ka (all dates in this article are uncalibrated radiocarbon ages), almost completely (up to 80–95%) dominated by thermophilic xerophiles, including true steppe species (10–20% of the whole assemblage), with a very low percentage of tundra beetles (Kiselyov, 1981). The assemblages show high diversity and abundance of steppe and meadow-steppe species (Table 6). Either meadow-steppe beetles, or a pill beetle *M. viridis* dominate all samples. These faunas represent the most 'steppic' dominated type of non-analog tundra-steppe assemblages.

Scattered similar assemblages of the same age are known elsewhere, but mostly within the Kolyma Lowland. For example, they are found in the Omolon-I section on the Kolyma River (Figure 7, no. 13; Figure 15; Table 3), Assemblages with more than 40% of meadow-steppe and steppe species are present here in the interval between 7.0 and 12 m depth (~23–18 ka) (Kiselyov et al., 1987). Tundra-steppe assemblages with extremely high numbers of *M. viridis* (Table 7), but less diverse and abundant steppe species occur below and above this interval.

Table 4 Characteristics of the most common and some indicative beetle species in the late Pleistocene assemblages in Northeastern Siberia

Family and species	% of all LP assemblages, where the species is found	Description	Taxonomic notes
<i>Ground beetles, Carabidae</i>			
<i>Pterostichus</i> (<i>Cryobius</i>) spp.	78	Most <i>Cryobius</i> are common in modern tundra and northern taiga and prefer boggy and wet habitats. <i>P. (C.) nigripalpis</i> Popp. is abundant today on Wrangel Island on dry patches with xerophilic vegetation (O. Khruleva, personal comm.)	Of numerous species in this subgenus, fossils of <i>P. (C.) ventricosus</i> Esch., <i>P. (C.) pinguedineus</i> Esch., <i>P. (C.) brevicornis</i> (Kirby), and probably <i>P. (C.) nigripalpis</i> Popp can be identified
<i>Curtonotus alpinus</i> (Payk)	92	Very widespread species from taiga to arctic tundra; prefers relatively dry and warm patches; feed on grasses. Hardly distinguishable fossils of a close species, <i>C. bokori</i> , can be present in some assemblages, but <i>C. alpinus</i> is much more common	In Europe and America this species is usually called <i>Amara alpina</i> Payk. In Russia, the subgenus <i>Curtonotus</i> , to which this species belongs, was raised to the generic level (Kryzhanovskiy, 1965; Kryzhanovskiy et al, 1995)
<i>Poecilus</i> (<i>Derus</i>) <i>nearcticus</i> Lth.	49	Modern specimens of <i>P. nearcticus</i> were collected on dry sandy slopes at a few sites in the Siberian Arctic and Alaska. In the Pleistocene, it was much more common, though not very abundant. It is a typical relict of the tundra-steppe beetle complex	
<i>Pterostichus</i> (<i>Tundraphilus</i>) <i>sublaevis</i> Sahlb.	35	This beetle lives now in tundra and prefers dry and warm habitats, but it is relatively rare. It was more widespread and abundant during the Pleistocene	
<i>Small carrion and round fungus beetles, Leiodidae</i>			
<i>Cholevinus sibiricus</i> (Jean.)	47	This is a rare species in modern tundra, preferring wet habitats. It is probably necro-, copro-, or/and detritophagous. <i>Ch. sibiricus</i> was more important in the Pleistocene tundra-steppe communities (Perkovsky and Kuzmina, 2001). Despite rather large populations of grazing mammals in tundra-steppe ecosystem, the revealed diversity of necro- and coprophagous beetles is very low. <i>Ch. sibiricus</i> might use this kind of food resources	Prior to 1999, this species was called <i>Cryocatops poppiusi</i> Jean., family Catopidae (Perkovsky, 1999)
<i>Rove beetles, Staphylinidae</i>			
<i>Tachinus arcticus</i> Motsch. and <i>T. brevipennis</i> Sahlb.	45	Both species live in wet tundra habitats, but <i>T. arcticus</i> is more abundant in the north, while <i>T. brevipennis</i> – in the south of the zone, and is probably more thermophilic	Earlier these fossils were referred to <i>T. apterus</i> Maekl (Kiselyov, 1981). Later, the identification was changed to <i>T. arcticus</i> . Now it is suspected that it can be a mixture of fossils of two different species
<i>Dung beetles, Scarabaeidae</i>			
<i>Aphodius</i> sp.	44	This dung beetle occurs in many Pleistocene sites and is clearly associated with tundra-steppe assemblages. Its well-preserved fossils have been found in buried ground squirrel nests	Probably an extinct species
<i>Pill beetles, Byrrhidae</i>			
<i>Morychus viridis</i> Kuzm. et Kor.	86	This beetle is a real symbol of the Pleistocene biota in Northeastern Siberia. Found in the majority of fossil assemblages, often in very high numbers, it is clearly associated with thermophilic steppe. At present, it lives in cold steppe-like habitats in the Kolyma Highlands, Chukotka, and Wrangel Island, called 'hemicycophytic steppe' after Yurtsev (1981). Modern habitats of <i>M. viridis</i> have extremely contrasting microclimatic conditions – very hot and dry in summer, and snowless and very cold in winter (Berman et al., 2001)	Before this species was described (Kuzmina and Korotyaev, 1987), its fossils were referred to <i>Chrysobyrrhulus rutilans</i> Motsh. (Kiselyov, 1981; Medvedev and Voronova, 1977)
<i>Leaf beetles, Chrysomelidae</i>			
<i>Chrysolina tolli</i> Jac.	25	This is one of the most cold-resistant species of beetles in the world. <i>Ch. tolli</i> was found in polar desert on Novaya Zemlya, Severnaya Zemlya and Novosibirsk Islands. In	The fossils were referred to <i>Ch. cavigera</i> Sahlb. until the recent revision by Bienkowski (1999), who showed that the modern arctic populations

(Continued)

Table 4 (Continued)

Family and species	% of all LP assemblages, where the species is found	Description	Taxonomic notes
		the tundra zone, it occupies different habitats, and feeds on Crucifera. <i>Ch. tolli</i> is found in many Pleistocene assemblages, though in low numbers, and is most common in northern sites	belong to <i>Ch. tolli</i> , while <i>Ch cavigera</i> is restricted to the Kamchatka Peninsula and the Okhotsk Sea coast
<i>Weevils, Curculionidae</i>			
<i>Sitona borealis</i> Kor.	46	This weevil feeds on legumes. Currently it lives mostly in meadow-steppe habitats in the taiga zone, but it also occurs on dry warm patches in tundra. It was more common in the Pleistocene than it is now	Formerly named as <i>S. ovipennis</i> Hochh. (Kiselyov, 1981), then <i>S. ovipennis borealis</i> Kor., this weevil is now considered as a separate species <i>S. borealis</i> Kor. (Korotyaev, 1996)
<i>Stephanocleonus eruditus</i> Faust	45	The main modern range of this weevil is Southern Siberia and Mongolia (mountain steppe). It is the most common steppe element in the Pleistocene assemblages. Having been very widely distributed in the Pleistocene, it survived in scattered relic steppe communities in the Kolyma-Indigirka Highlands (Berman et al., 2001). This species is a good indicator of relatively high summer temperature (Berman and Alfimov, 1993)	
<i>Lepyrus nordenskiöldi</i> Faust	46	This weevil lives on willow, rarely on birch, and is common in tundra, taiga, and relic steppe modern environments, but prefers drier habitats with sandy soil. Thus, being very often a single representative of shrub insect group in the Pleistocene assemblages, <i>L. nordenskiöldi</i> can be considered as an indicator of relatively dry environment, although the authors count this species among the forest-tundra species	
<i>Hypera ornata</i> (Cap.)	48	The distribution and ecology of this weevil are similar to those of <i>Sitona borealis</i> (see above)	Former name <i>Phytonomus omatus</i> Cap.
<i>Isochnus arcticus</i> (Kor.)	44	This species lives on willows, but its distribution is restricted to the typical tundra subzone. It is most abundant on Wrangel Island, but was also found on the Taimyr Peninsula, in western Chukotka and northern Alaska. It can be found in the Pleistocene assemblages of different age in small numbers, but became the dominant species during the Last Glacial Maximum at some (mostly northern) sites	Former name <i>Rhynchaeus arcticus</i> Kor.

The *M. viridis*-dominated LW assemblages were distributed much more widely than just in the Kolyma Lowland. They are also known from the Yedomas sections in the Indigirka and Khroma valleys (Table 3), and much further north, in sites from the Lena Delta. In the Mamontovy Khayata (MKh) section (Figure 7, no. 3), they form a series of samples associated with the termination of the LW (IFZ 4) and dated about 14–12

¹⁴C ka (Figure 21). *M. viridis* exclusively dominates four samples (50–60%). In the Lena Delta, these samples represent the highest content of *Morychus*, steppe and other xerophilic species during the whole Weichselian, so this stage has been recognized as the Late Glacial event, a brief interval of higher summer temperatures and drier environments in this Arctic region (Sher et al., 2005).

(a–f), (h–l), (n) Lena Delta region; (m, o, p) Chukotka. Light microscope photographs, scale bar equals 1 mm.

The LGM insect assemblages in the Lena Delta are strikingly different from those in the Kolyma Lowland. In the MKh section, they are recognized as IFZ 3 (Figure 21). Of nine samples within the range of 24–14 ka, six are strongly dominated by Arctic tundra insects (40–67%), mainly *I. arcticus*. Xerophilic insects constitute only 1.5–3%, with a maximum of 5% of the fauna – the lowest values in the whole Weichselian. Even the ubiquitous *M. viridis* was encountered in only

four of nine samples (below 2%). True steppe insects were totally absent between ~23 and 20 ka and comprised just 1–3% of the faunas in the other samples. These peculiar assemblages (Arctic type of tundra-steppe) are interpreted as evidence of a very cold climate with dry summers (Sher et al., 2005). This reconstruction is corroborated by the plant macrofossil assemblages from the same sites (Kienast et al., 2005).

Table 5 Ecological groups of insects used for quantitative comparison of fossil assemblages

Ecological group and symbol	Group description	Main species
Steppe (st)	The members of this group live today in the steppe zone, some in the mountain belt of southern Siberia and Mongolia. Some of them survive under special microclimatic conditions in the relic steppe patches in NE Asia. However, the presence of any of these species can be considered evidence of unusually high summer temperatures (Berman et al., 2001)	Ground beetles <i>Harpalus pusillus</i> Motsch., <i>Cymindis arctica</i> Kryzh. et Em., leaf beetles <i>Chrysolina perforata</i> Gebl., <i>Ch. brunnicornis bermani</i> Medv., <i>Galeruca interrupta circumdata</i> Duft. weevils <i>Stephanocleonus eruditus</i> Faust, <i>S. fossulatus</i> F-W. <i>S. incertus</i> T-M.
Meadow-steppe (ms)	This group consists of species common in dry (steppe-like) meadows in various ecosystems. They are more cold-tolerant than the previous group. They survive today even in the tundra zone, on the warmest localities	Ground beetles <i>Harpalus vittatus kiselevi</i> Kat. et Shil, soft-winged beetle <i>Troglocollops arcticus</i> L. Medv., the leaf beetle <i>Chrysolina arctica</i> Medv., weevils <i>Phyllobius kolymensis</i> Kor. et Egorov, <i>Coniocleonus cinerascens</i> Hochh., <i>C. ferrugineus</i> Fahr., <i>C. astragali</i> T.-M. et Kor.
Insects of hemicyrophytic steppe (ss)	Hemicyrophytic steppe (Yurtsev, 1981) is a cold steppe-like environment, dominated by a few species of xerophilic sedges and mosses. It has extremely contrasting microclimatic conditions – very hot and dry in summer, and snowless and very cold in winter. It occurs on very dry, snowless hill tops in the taiga or, rarely in tundra zone; (Berman et al., 2001). This environment is currently found in the Kolyma Highlands, Chukotka, and Wrangel Island. It is believed to have many features in common with some kinds of Pleistocene tundra-steppe	Pill beetle <i>Morychus viridis</i> Kuzm. et Kor. is the only representative of this group
Xerophilic insects of various habitats (ks)	Insects of xerophilic habitats of tundra, taiga, and steppe	Ground beetle <i>Notiophilus aquaticus</i> L., dung beetle <i>Aphodius</i> sp.
Insects of dry tundra habitats (dt)	The insects of this group usually occupy the warmest sites in the tundra zone, most commonly well-drained sites with diverse grasses and herbs. Most of them do not reach the Arctic tundra today, but they quite often occupy parts of the taiga zone, in suitable biotopes. Some species can also be found today on relict steppe patches	Ground beetles <i>Bembidion dauricum</i> Motsch., <i>Poecilus (Derus) nearcticus</i> Lth., <i>Pterostichus (Petrophilus) abnormis</i> Sahlb., <i>P. (Tundraphilus) sublaevis</i> Sahlb., <i>Stereocerus haematopus</i> (Dej.), <i>Curtonotus alpinus</i> Payk., <i>Amara interstitialis</i> Dej., <i>A. glacialis</i> Mnnh., <i>Dicheirotichus mannerheimi</i> Sahlb., leaf beetle <i>Chrysolina marginata borealis</i> Medv., weevils <i>Mesotrichapion wrangelianum</i> Kor., <i>Hemitrichapion tschernovi</i> T.-M., <i>Sitona borealis</i> Kor., <i>Hypera ornata</i> Cap., <i>H. diversipunctata</i> Schrank., <i>Lepidophorus thulius</i> (Kiss.)
Insects of typical and arctic tundra (tt)	Most cold-resistant species from different habitats in the Arctic	Leaf beetles <i>Chrysolina tolli</i> Jac., <i>Ch. subsulcata</i> Mnnh., <i>Ch. bungei</i> Jac., weevil <i>Isochnus arcticus</i> Kor.
Insects of mesic tundra habitats (mt)	The insects of this group are now found in different, mostly wet and relatively cold habitats in tundra; some occur on boggy patches in forest tundra	Ground beetles <i>Carabus truncaticollis</i> Esch., <i>Blethisa catenaria</i> Brown. <i>Diacheila polita</i> Fald., <i>Pterostichus (Cryobius) ventricosus</i> Esch., <i>P. (Cryobius) pinguedineus</i> Esch., <i>P. (Cryobius) brevicornis</i> (Kirby), <i>P. (Lenapterus) vermiculosus</i> Men., <i>P. (Lenapterus) costatus</i> Men., <i>P. (Lenapterus) agonus</i> Horn., small carrion beetle <i>Cholevinus sibiricus</i> (Jean.), rove beetles <i>Olophrum consimile</i> Gyll., <i>Tachinus arcticus</i> Motsch., <i>T. brevipennis</i> Sahlb., leaf beetle <i>Chrysolina septentrionalis</i> Men
Shrub (sh)	These beetles feed on shrubs, mostly willows, except dwarf shrubs of typical and Arctic tundra	Leaf beetles <i>Chrysomela blaisdelli</i> Van Dyke, <i>Phratora polaris</i> Schn., <i>Ph. vulgatissima</i> L., weevils <i>Lepyrus nordenskioldi</i> Faust, <i>L. gemellus</i> Kirby, <i>Dorytomus rufulus amplipennis</i> Tourn., <i>Isochnus flagellum</i> Erics
Meadows (me)	Mostly in the forest zone, although some species can occur on tundra meadows	Pill beetles <i>Byrrhus fasciatus</i> Forst., <i>Cytilus sericeus</i> Forst., click beetle <i>Hypnoidus hyperboreus</i> Gyll., leaf beetles <i>Bromius obscurus</i> L., <i>Phaedon concinnus</i> Steph., <i>Ph. armoraciae</i> L., weevils <i>Phyllobius virideaeris</i> Laich., <i>Sitona lineellus</i> Bonnd
Taiga (ta)	Tree-associated insects and insects whose range is restricted to the taiga zone	Ground beetle <i>Pterostichus (Petrophilus) magus</i> Man., click beetle <i>Denticollis varians</i> Germ., weevils <i>Hyllobius piceus</i> DeG., <i>Pissodes insignatus</i> Boh., <i>P. irroratus</i>

(Continued)

Table 5 (Continued)

Ecological group and symbol	Group description	Main species
Riparian (ri)	These insects live near water in several zones, but most of them are restricted to the taiga zone	Reitt., bark beetles <i>Ips cembrae</i> Heer, <i>Polygraphus</i> sp., ants <i>Leptothorax acervorum</i> Fabr., <i>Formica gagatoides</i> Ruzs., <i>Camponotus herculeanus</i> L. Ground beetles <i>Pelophila borealis</i> Payk., <i>Nebria frigida</i> Sahlb., <i>Elaphrus lapponicus</i> Gyll., <i>E. riparius</i> L., <i>Dyschiriodes nigricornis</i> Motsch., <i>Bembidion umiatense</i> Lindrt., <i>Agonum quinquepunctatum</i> Motsch., rove beetles <i>Stenus</i> sp., lady-bird <i>Hippodamia arctica</i> Schneid., leaf beetles <i>Donacia</i> sp., <i>Hydrothassa hannoverana</i> F., weevils <i>Phytobius leucogaster</i> Marsh., <i>Tournotaris bimaculatus</i> F., bugs of Saldidae family
Aquatic (aq)	These insects live in various tundra and taiga water bodies, mostly small ponds	Predaceous diving beetles <i>Hydroporus acutangulus</i> Thoms., <i>Agabus moestus</i> (Curt.), <i>Colymbetes dolabratus</i> (Payk.), whirligig beetle <i>Gyrinus opacus</i> Salb. water scavenger beetles <i>Helophorus splendidus</i> Sahlb., <i>Hydrobius fuscipes</i> F., water bug <i>Sigara</i> sp.
Others (oth)	Insects of intrazonal habitats (such as plant litter, or fungi) and fossils unresolved to a species (of genera with ecologically various members)	Small carrion beetle <i>Cyrtoplastus irregularis</i> Rtt., carrion beetle <i>Thanatophilus dispar</i> Hbst., rove beetles <i>Eucnecus</i> sp., <i>Lathrobium</i> sp., <i>Quedius</i> sp., lady-bird <i>Coccinella</i> sp., minute brown scavenger beetle <i>Corticaria</i> sp.

23 000	4.29	39.64	41.79
24 000	11.45	76.72	5.34

A similar assemblage is known from the Buor-Khaya exposure on the Central Lena Delta (from the upper part of the Ice Complex), where it is dated about 17 ka (Kuzmina, 2001). Outside the Lena Delta, the Arctic-type tundra-steppe fauna was found in a single, poor sample from the LW Ice Complex in the northern Yana-Indigirka Lowland (Volchya River, 71.7° N).

Thus, during the LGM, tundra-steppe insect faunas of the Arctic type existed only in the northernmost parts of the continent. Further south, they included increasingly thermoxerophilic and steppe elements. For example, at the Krasivoye site on the Malyy Anyuy River (68.3° N; Figure 7, no. 15; Table 3), the Ice Complex assemblage dated about 19 ka was dominated by dry tundra (29%) and xerophilic beetles (53%), with sedge-steppe, meadow-steppe, and true-steppe components each comprising over 15%. Assemblages with an even more pronounced xerophilic component are common in sections (or their members) that are tentatively referred to the LW, all over

Northeastern Siberia. Many exposures in the Kolyma Lowland have yielded faunas with 65–90% xerophiles (alternatively dominated by sedge-steppe or meadow-steppe beetles) in the upper part of the Ice Complex (Duvanny Yar, Lakes Yakutskoye, and others – Figure 7, no. 8; Figure 9; Table 3). In the Indigirka Lowland, the LW sites on the Khroma, Indigirka (Suturuokha), and Yana Rivers are also dominated by xerophiles (60–80%), with *M. viridis* dominating the whole spectrum (30–60%). Similar kinds of insect assemblages (with xerophiles forming 50–95% of the whole spectrum) have been described from the upper part of the Ice Complex of Ayon Island (Utatgyr Suite, Northwestern Chukotka, ~69.5° N – Figure 7, no. 10; Table 3), but here they have an even stronger contribution of meadow-steppe or/and true-steppe species (30–90%). In contrast to this, at the eastern edge of Asia, closer to the Pacific, the steppe component in the LGM faunas is much less pronounced, or absent altogether. In southern Chukotka, for example (the Ice Bluff section on the

Table 8 The insect assemblages of the presumed 'Last Interglacial' age in Northeastern Siberia

Unit	Location	Sediment description	Insect assemblages
Kyl-Bastakh layers	Khroma River (Figure 7, No. 17)	Organic-rich filling of ice-wedge pseudomorphs (the casts of former ice wedges), intruding the top of the Khroma Suite, presumably referred to the late middle Pleistocene, and overlain by the Yedoma Suite (Ice Complex)	Three fossil assemblages are dominated by tundra species (>30%), both mesic and xeric, and the percentage of forest-tundra species is probably the highest elsewhere in the regional record (about 10%). Among the latter, such forest zone species as <i>Phyllobius virideaeris</i> Laich. (a meadow weevil) and <i>Carabus maeander</i> Fisch. (a taiga ground beetle), shrub leaf beetles <i>Chrysomela lapponica</i> L. and <i>Phratora polaris</i> Schn. are recorded. At the same time, the thermophilic xerophiles comprise 15–20% of the whole fauna, and among them are not only the 'sedge-steppe' species <i>Morychus viridis</i> Kuzm. et Kor. and the dung beetles <i>Aphodius</i> sp. nov., but true steppe insects, such as the ground beetles <i>Harpalus pusillus</i> Motsch. and <i>Cymindis arctica</i> Kryzh. et Em., a leaf beetle <i>Chrysolina perforata</i> Gebl. and a weevil <i>Stephanocleonus foveifrons</i> Chev. Remarkably, the assemblages include a few specimens of Arctic tundra leaf beetle <i>Chrysolina subsulcata</i> Mnnh. and an arctic weevil <i>Isochnus arcticus</i> Kor. They also contain a large number of hydrophilic beetles, which is commonly found in peat deposits
Kuobakh unit	Alazeya River (Figure 7, No. 5)	A peat layer and organic-rich ice-wedge pseudomorphs are observed between the late middle Pleistocene Maastakh Suite and the Yedoma Ice Complex	Similar to the Kyl-Bastakh, the assemblages combine a high percentage of hydrophilic and tundra species with a large number (up to 33%) of forest-tundra insects. The latter include mostly the ant <i>Formica gagatoides</i> Ruzs. and various meadow species from the forest zone, such as a click beetle <i>Hypnoidus hyperboreus</i> Gyll., an ant-like beetle <i>Anthicus ater</i> Pz., a leaf beetle <i>Phaedon concinnus</i> Steph., and a weevil <i>Phyllobius virideaeris</i> Laich. Xerophiles comprise up to 8–10% of the faunal assemblages, but do not include steppe species
Krest-Yuryakh unit	Bolshoy Lyakhovsky Island (Figure 7, No. 4)	Two layers of organic-rich ice-wedge pseudomorphs	The unit is in the same stratigraphic position, but the locality is much further north, so it is dominated by mesic tundra species (35–45%) and dry tundra insects (20–30%). However, the Krest-Yuryakh assemblages include both forest-tundra species (2–5%) and up to 10–20% of thermophilic xerophiles, including a few occurrences of steppe species, such as the ground beetle <i>Cymindis arctica</i> Kryzh. et Em., and the weevils <i>Stephanocleonus eruditus</i> Faust and <i>S. fossulatus</i> F.-W.

Main River, [Figure 7](#), no. 12; [Table 3](#)), throughout the interval from 25 to 15 ka, all groups of xerophilic insects rarely reach 30% (usually below 10%) and are mostly represented by *M. viridis*. On the other hand, arctic beetles are abundant in assemblages dated around 21 ka (up to 40%). This is probably indicative of a milder (Pacific) version of the cold-adapted (Arctic-type) LGM faunas.

Middle Weichselian insect assemblages

The Middle Weichselian interval (from about 50 to 25 ka) was traditionally considered as a 'warmer climate interstadial' interval in Northern Asia (called 'Karginsky'), including several cycles of cooling ([Kind, 1974](#)). In many natural sections, where organic-rich deposits (usually peat) occurred under the Ice Complex, or inside it, or separating two 'Ice Complexes' (two members with their own system of polygonal ice wedges), these peats have been ^{14}C dated to 35–40 ka. The pollen spectra of these layers usually show a high percentage of arboreal (mostly shrub) pollen, in contrast to the completely grass-herb-dominated spectra of the Ice Complex itself. In recent years, however, several important new discoveries have been made about this interval. First, repeated ^{14}C dating showed that most of the samples that yielded ^{14}C ages near 35 ka and older, were indeed much older and could actually represent ages beyond the ^{14}C age range ([Sher and Plakht, 1988](#)). Second, it was shown that the 'Karginsky' sections in the type area (Lower Yenisey) had been misinterpreted, and their dating was erroneous. In fact, they turned out to be much older, probably as old as the last interglacial ([Astakhov, 2001](#)). Third, new radiocarbon ages from the regional type sections of the 'Karginsky Interstadial' in Northeastern Siberia also yielded much older dates ([Sulerzhitsky, 1998](#)). Finally, the multidisciplinary study of a continuous section through most of the LW in the Lena Delta, well dated by ^{14}C , revealed a completely different regional history of this period ([Andreev et al., 2002](#); [Schirmermeister et al., 2002](#)). The study of the detailed record of fossil insect assemblages through this sequence allowed us ([Sher et al., 2005](#)) to suggest a very different reconstruction of Middle Weichselian environments.

It has been shown that tundra-type insect assemblages persisted in the Lena Delta throughout the Middle Weichselian interval, with a variable, but almost consistent presence of xerophilic species. Although today the northern limit of taiga (sparse larch forest) is not far south of the site, no fossil assemblages of the forest or even forest-tundra type have ever been found here. The contribution of xerophilic species was more noticeable in the first half of the Middle Weichselian interval, especially in the assemblages ^{14}C dated about 45–48 ka, when they reached 30–50%. The possibility cannot be excluded, however, that these assemblages are actually Early Weichselian in age. Taken together with the dry tundra species contribution, the percentage of relatively thermophilic forms gradually decreased from 48 to 34 ka (IFZ 1; [Figure 21](#)). At the same time, the contribution of arctic species increased, and by 34 ka it almost reached LGM levels (more than 50%). The second half of the Middle Weichselian (34–24 ka, IFZ 2 on [Figure 21](#)) is marked by the lowest levels of xerophilic species (usually below 7%) and the predominance of mesic tundra insects, sometimes with a high contribution of arctic species. This sequence, the most complete in Northern Asia, is

interpreted as a gradual decrease in summer temperatures toward the LGM, probably accompanied by some increased moisture. However, these moisture levels did not reach the levels observed in modern tundra environments. This indicates that during the Middle Weichselian, the climate was more continental than today in this coastal area. This conclusion is in agreement with various observations that sea level in the Eastern Arctic remained low at that time.

Several sites in more southern areas of Northeastern Siberia yielded representative insect assemblages obtained from the Ice Complex and associated with late Middle Weichselian ^{14}C dates. For example, in the Shamanovo Yedomia section on the Indigirka River ([Figure 7](#), no. 16; [Table 3](#)) a rich insect sample came from the unit dated by *in situ* grass roots at 29 300–32 900 years BP ([Kaplina et al., 1980a,b](#)). The assemblage is dominated by *M. viridis* and other xerophilic insects (66%) and dry habitat species prevail in the tundra group ([Kiselyov, 1994](#)). On the Khroma River ([Figure 7](#), no. 17; [Table 3](#)), the assemblage dated 28 800 years BP ([Kaplina et al., 1983](#)) has the same percentage of xerophilic species, but *M. viridis* is much more abundant, while the contribution of steppe species is low.

Interesting assemblages, presumably associated with the Middle Weichselian, were found in the Primorsky alas section in western Chukotka ([Figure 7](#), no. 18; [Table 3](#)). The sampled unit contains tree birch wood, and is dated more than 27 870 years BP ([Kiselyov, 1994](#)). The assemblages ([Table 7](#)) include unusually high percentages of forest-tundra species (7%), comprising such forest inhabitants as the rove beetles *Acidota* sp., *Arpedium* sp., *Xantholinus* sp., *Anthobium* sp., and *Bolitobius* sp., as well as the birch-associated weevil *Betulapion simile*. On the other hand, these assemblages contain high percentages of *M. viridis* and a few true steppe beetles. A peat layer from about 12 m higher in the section is dated at 24 800 ± 400 years BP. Two insect assemblages from this unit are similar to the lower ones, but show even higher percentages of forest-tundra beetles (up to 12%) represented by the same species. The steppe, meadow-steppe beetles and *M. viridis* are still present, although in lower numbers.

However, in southern Chukotka, insect assemblages from the same age interval (34–24 ka) (Ice Bluff locality; [Figure 7](#), no. 12; [Figure 17](#); [Table 3](#)) do not contain any forest beetles ([Kiselyov, 1994](#)). The percentage of xerophilic species is high (38%), mostly at the expense of dung beetles (*Aphodius* sp. nov.?) and *M. viridis*. True steppe and meadow-steppe species are represented only by single specimens.

Early Weichselian insect assemblages

Taking into account the dating problems, it is difficult to confidently assign any fossil insect assemblage to the Early Weichselian interval. On the other hand, the lower parts of many thick Ice Complex sections may belong to this time interval. For example, in the key section of the Ice Complex of Duvannyy Yar ([Figure 7](#), no. 8; [Figure 9](#); [Table 3](#)), a large number of infinite ^{14}C dates (>45 ka) in the lower part of the section (mixed with dates in the range of 33–45 ka) may suggest an Early Weichselian age ([Sher, 1991](#)). The same is possible for the Oyagosskiy Yar assemblage ([Figure 7](#), no. 19; [Table 3](#)) and the sections on the southern coast of Bol. Lyakhovsky Island ([Figure 7](#), no. 4; [Table 3](#)). In the Kolyma

Lowland, the insect assemblages from the lower parts of Ice Complex sections are dominated by *M. viridis* with a small admixture of other xerophiles (usually below 10%) (Duvanny Yar; Sher et al., 1979). However, the northern localities, such as Oyagos, Lyakhovsky, or Nagym in the Lena Delta (Figure 7, no. 1; Table 3), are mostly dominated by tundra species, sometimes with a high percentage of Arctic tundra species or mesic tundra inhabitants. The total percentage of all xerophiles is usually below 15%, and the main role in this group is played by *M. viridis*, while true steppe species are either extremely rare or completely absent (Kuzmina, 2001).

Thus, it may be concluded that the same regularities in spatial distribution of insect assemblages in the LW existed during Early Weichselian time.

'Last Interglacial' insect assemblages

The problems of recognition of Last Interglacial sediments were discussed above (cf. also Sher, 1991). Tentatively, the authors refer some parts of particular complex sections to this interval. These sediments overlie sediments of presumed middle Pleistocene age and they underlie the LP Ice Complex. Also, they contain abundant organic remains. Such localities usually represent buried alas complexes (Table 3). The characteristics of insect assemblages forming three of them are shown in Table 8.

The most remarkable character of all these assemblages is the extreme heterogeneity of their ecological composition, combining representatives from practically all ecological groups. Many species comprising those assemblages do not occur together today. At present, their ranges are often separated by many hundreds of kilometers. This is especially evident for the northernmost assemblages (Bolshoy Lyakhovsky Island), where about 80% of identified insect species currently live much further south. This indicates the non-analog character of the assemblage, which certainly existed in a warmer climate than today, with higher summer and probably somewhat higher winter temperatures. According to the paleobotanical data (Andreev et al., 2004), summer temperatures could have been 4–5 °C higher than present. In general, the climate was more continental than today on Lyakhovsky Island, but less so than during the Weichselian interval. Compared with the modern environment of the island, the humidity was certainly lower in summer, but probably somewhat higher in winter. A thicker snow cover would have allowed the growth of tall shrubs at this high latitude.

Summary

This review demonstrates the large scope of the Pleistocene beetle research in Northeastern Siberia during the recent years. However, many gaps remain in the knowledge shared in this article and some significant problems are still unsolved. Evidently, the characterized beetle faunas are peculiar, but the authors have a poor idea of how far south and west they were distributed. Very few fossil assemblages are known south of the Arctic Circle in this region, and none to the west of the Lena Delta. They also have serious problems with the dating of fossil assemblages older than 30 ka. The authors believe that future research should be concentrated on continuous sedimentary

sequences, such as the Bykovsky section, and this research must be a part of broad multidisciplinary projects. Recent experience shows that successful projects of such kinds must be based on international collaboration.

Introduction

Insect analyses carried out from Holocene sequences are relatively rare in Britain and Northern Europe, in contrast to late Pleistocene and Late Glacial sequences which have been thoroughly investigated during the last 50 years. Therefore, the early to mid-Holocene history of the Coleopteran (beetle) fauna in Western Europe relies for the most part on the analysis of scattered assemblages, obtained from natural or seminatural deposits. Late Holocene studies, especially from the historical period, are much more abundant, but the vast majority of data concerning this period derive from analyses carried out in archaeological sites from anthropogenic contexts and are dominated by synanthropic insects. These studies provide a wealth of data, mainly concerning the living conditions of man. However, they offer relatively restricted information on past environments, although some archaeological deposits have yielded beetle assemblages providing a detailed picture of the landscape surrounding human settlements (see, e.g., Ponel et al., 2000). Nonanthropogenic organic deposits contemporaneous with human occupation are usually more effective to reconstruct the environmental history in a wider area (see, e.g., the reconstruction of the landscapes along the Thames Valley from the Mesolithic to the Late Bronze Age by Elias et al., 2009). A further complication hampering the paleoenvironmental interpretation of Postglacial beetle records is the growing influence of man on natural ecosystems from the mid-Holocene onwards, through forest clearance, development of agriculture, pastoralism, and fragmentation of habitats. These landscape modifications make it difficult to disentangle the respective role of climate and human impact on beetle faunas.

Considering the wide range of subjects treated by Quaternary entomologists and archaeoentomologists from Postglacial beetle records, this article is necessarily focused on a selection of issues, such as changes in beetle faunal assemblages at the onset of the Holocene and their paleoclimate and paleoenvironmental implications, impact of human activities on landscapes and beetles (especially the effect of forest clearance on saproxylophagous (sap- and wood-feeding) species), and reconstruction of paleoenvironmental changes in Mediterranean mountains from continuous sedimentary sequences.

Climatic Context

The Quaternary is marked by a climatic cyclicity of cold and warm periods (glacial–interglacial), and by the appearance and evolution of humans. The Postglacial or Holocene Epoch that started about 11 000 years ago is the last warm period of the Quaternary (the current interglacial) and can be considered an approximate replica of the penultimate interglacial, the Eemian (130 000–110 000 BP). The

Holocene interglacial has been deeply affected by human impact on natural ecosystems, especially in its second half. The glaciation that immediately preceded the Holocene is biologically important since glacial conditions that prevailed at that time (60 000–15 000 BP) eradicated most of temperate biota from Central and Northern Europe, including insects, which were relegated to temperate refugia (probably located in Mediterranean peninsulas). The insect recolonization of Europe induced by the Holocene warming is the result of the northwards shift of biota from these southern ‘reservoirs.’ Far from being a steady process, the transition from the last glaciation to the current interglacial, approximately 15 000 and 10 000 BP, was marked by a complex series of sharp warm and cold events. This period of climatic instability, commonly named the Late Glacial, includes a first climatic warming between 15 000 and 13 000 BP (the Oldest Dryas), a predominantly warm period between 13 000 and 10 700 BP, the Late Glacial interstadial, and a short but drastic climatic cooling between 10 700 and 10 300 BP (the Younger Dryas). The Late Glacial is particularly well documented from beetle records (Coope, 1994), and one of the major achievements of Quaternary Entomology is the demonstration of the amazing rapidity of the Late Glacial warming at 13 000 BP, since mean July temperatures in Britain rose by about 1 °C per decade (for a total of about 7 °C), and corresponding winter temperatures rose by about 20 °C (Atkinson et al., 1987). Following the second episode of rapid warming (by 10 000 BP), temperate climate conditions prevailed during most of the Holocene.

Vegetation History

Deciduous forest (with hazel, oak, elm, and linden) spread throughout much of Europe by 10 000 BP. Based on paleobotanical reconstructions, a thermal optimum is identified between 8000 and 6000 BP, and it is at that time that an unprecedented event, the Neolithic ‘revolution,’ arose in the Near East and expanded quickly into Europe, inducing forest clearance and agriculture. By 5000 BP, the ‘Urwald,’ or primitive forest, started to shrink in most of lowland Europe, including Britain. ‘Slash and burn’ cultivation practices induced a deep change in plant communities, as indicated by pollen analysis: there was a decline of many forest taxa, and a rise of heliophilous plants (plants adapted to full sunlight in open ground situations) and many weeds (*Plantago*, *Urtica*, plants associated with disturbance). The Iron Age (around 3500–2500 BP) corresponds with a time of marked human population growth, furthering the development of agricultural landscapes. By 2500 BP the intensification of agricultural disturbance on natural vegetation structures is superimposed with a climate change at the Subboreal (warm/dry climate)–Subatlantic (cool/wet climate) transition.

The Onset of the Holocene: Beetles at the Younger Dryas–Preboreal Transition

Shortly before the climatic and environmental changes that occurred in Europe during the early Holocene (Preboreal interval), an arctic/alpine beetle fauna, including many species restricted today to very high latitudes in arctic regions of Scandinavia and northern Russia, thrived in Britain and in most of Europe. This cold-adapted fauna is associated with the Younger Dryas (from 10 700 to about 10 300 BP), a short but intense cold event. Most of these species were already present at the end of the last glaciation, about 15 000 BP, but were temporarily eradicated from mid-latitudes by the warm episode of the Late Glacial interstadial. This extremely cold-adapted fauna (Figure 1) includes many characteristic species such as:

<i>Nebria nivalis</i>	<i>Amara alpina</i>
<i>Diacheila arctica</i>	<i>Pterostichus middendorffi</i>
<i>Elaphrus lapponicus</i>	<i>Agonum consimile</i>
<i>Dyschirius septentrionum</i>	<i>Agonum sahlbergi</i>
<i>Bembidion dauricum</i>	<i>Helophorus fennicus</i>
<i>Bembidion fellmanni</i>	<i>Helophorus glacialis</i>
<i>Bembidion hasti</i>	<i>Helophorus obscurus</i>
<i>Bembidion hyperboreaum</i>	<i>Arpedium brachypterum</i>
<i>Bembidion lapponicum</i>	<i>Boreaphilus henningianus</i>
<i>Bembidion mckinleyi</i>	<i>Olophrum boreale</i>

Some Siberian and eastern Asiatic species (*Pterostichus magus*, *Helophorus jacutus*, *Tachinus jacuticus*) suggest a climate more continental than today. At the time of the Younger Dryas the landscape in most of Europe was comparable to an arctic tundra, and the average July temperature was close to 10 °C.

At the close of the Late Glacial, by 9500 BP, this very cold-adapted fauna was completely and rapidly eradicated. In the British Isles and certainly also in most of Central and Northern

Europe, the representatives of the arctic–alpine fauna disappeared suddenly, to be rapidly replaced by a thermophilous (warm-adapted) fauna, including various saproxylophagous species (beetles associated with mature old trees). The early Holocene horizons from the sedimentary sequence at Holywell Coombe (Coope, 1998) yielded such Postglacial assemblages, with many rather thermophilous Coleoptera, such as:

<i>Clivina fossor</i>	<i>Prosternon tessellatum</i>
<i>Bembidion octomaculatum</i>	<i>Denticollis linearis</i>
<i>Bembidion biguttatum</i>	<i>Melasis buprestoides</i>
<i>Patrobus atrorufus</i>	<i>Eucnemis capucina</i>
<i>Pterostichus strenuus</i>	<i>Dirhagus pygmaeus</i>
<i>Pterostichus minor</i>	<i>Anaglyptus mysticus</i>
<i>Platynus assimilis</i>	<i>Pogonochaerus hispidulus</i>
<i>Licinus depressus</i>	<i>Taphrorychus villifrons</i>
<i>Megarthritis hemipterus</i>	<i>Coenorhinus aeneovirens</i>
<i>Olophrum piceum</i>	<i>Rhyncholus elongatus</i>
<i>Lesteva heeri</i>	

This faunal change clearly suggests the rapid establishment of a climate marked by temperatures as high, or even higher, than those of the present day. Elsewhere in Europe the same pattern is also recorded from a variety of sites scattered from Scandinavia (Lemdahl, 1997) to Central France (Ponel and Coope, 1990), Switzerland (Lemdahl, 2000), and Italy (Ponel, 1997).

The very rich fauna from Lea Marston, analyzed by Osborne (1974) and dated to about 9500 BP, is especially interesting since most of the beetles from the assemblages are rather thermophilous woodland species (such as *Calosoma inquisitor* and *Xylodrepa quadripunctata*, predators on tree-feeding caterpillars). This fauna is compatible with a mixed oak forest, and therefore suggests a warm climate with summer temperatures on the order of 16–17 °C, comparable with that of southern England or southern Sweden today. However, pollen evidence shows that the landscape was dominated at that time by willow and birch woodland, not by thermophilous trees. This time lag between the colonization of warm-adapted beetles during a period of very rapid climate amelioration and the northwards thermophilous tree expansion is analogous to that described by Coope and Brophy (1972) at the onset of the Late Glacial interstadial and should be attributed to the interaction of various factors, such as tree dispersal rate, location of refuges, soil maturation, competition, and ecological succession. A similar observation is made by Coope (1998) at Holywell Coombe: the lithological boundary between clayey Late Glacial ‘cold’ deposits and more organic Postglacial ‘warm’ deposits is not synchronous with the faunal change, since the first occurrences of thermophilous beetles are recorded earlier, that is to say below the lithological boundary. Again, beetles seem to respond more rapidly than plants to the warming and appear in the area before the rise in organic sedimentation triggered by the expansion of vegetation.

Figure 1 *Helophorus glacialis* (Coleoptera: Helophoridae). This cold-adapted boreomontane water beetle lives at the edge of melting snow patches at sea level in the north of its distribution and at high altitude in Mediterranean mountains. It is abundant in cold periods during the Late Glacial and becomes increasingly scarce in most of European sedimentary sequences at the onset of the Holocene.

Climatic Indications from Coleoptera During the Holocene

The recent synthesis by Mayewski et al. (2004) provides evidence for a highly variable climate during the Holocene and reveals at least six periods of rapid climate change at a global

scale. Concerning beetles however, as clearly stated by Coope (1986), "it is easy to demonstrate that many species of coleoptera have had their geographical ranges drastically altered during this time, but it is much more difficult to sort out the contributions made by changes in climate from those imposed by human interference." The quantification of Holocene climate changes reconstructed from beetle data is therefore a relatively neglected issue in spite of the high number of sites investigated, especially in the British Isles. Computerized climatic reconstruction methods such as mutual climatic range have rarely been used.

Despite these limitations, several attempts to retrace Holocene climate changes from beetle records have been made in Britain (Buckland and Wagner, 2001; Kenward, 2004; Osborne, 1976, 1997). Some useful inferences may be drawn from beetles not associated with dead wood habitat, since saproxylophagous taxa are more likely to respond to forest clearance by man than to climate changes. After the initial rapid rise in temperature 10 000 years ago, the following period is rather poorly known and beetle assemblages do not show any obvious evidence of significant climate fluctuations until about 4830 BP. At that time a climatic deterioration is suggested by the occurrence in the British Midlands (Kelly and Osborne, 1965) of several 'northern' Coleoptera (*Bembidion atroviolaceum*, *Sphaerites glabratus*, *Tropiphorus obtusus*, *Barynotus squamosus*). This cool phase seems relatively short since Girling (1984) described an early Neolithic beetle assemblage (5000 BP) suggesting temperatures slightly warmer than today. This fauna contained the thermophilous and continental ground beetle species *Oodes gracilis*.

Younger assemblages do not indicate thermal conditions very different from those of the present time. A marked change is recorded in Bronze Age assemblages (Osborne, 1982, 1988), with the appearance of an apparently warm fauna including several dung beetles (mainly *Onthophagus*) that today are extremely rare or even extinct in Britain. These assemblages probably suggest a thermal climate warmer than today during the Bronze Age around 4000–3000 BP. The late Iron Age site of Fisherwick, at about 2130 BP (Osborne, 1979) yielded fossils of the dung beetle *Heptaulacus testudinarius*, again a very southern species in Britain, and is interpreted as evidence for a warm climate. However, the climatic significance of these dung beetle occurrences remains a matter of debate since it is possible that pastures may have suffered of human perturbations, leading to the retraction or eradication of beetles associated with old grasslands (Buckland and Dinnin, 1993).

The vast majority of records for the historic period have been obtained from urban anthropogenic contexts such as heated buildings, allowing many thermophilous and synanthropic species to survive outside their natural range and blurring the climatic signal. Nevertheless, Kenward (2004) suggests that a careful interpretation of data concerning the nonsynanthropic elements included in insect assemblages from archaeological occupation deposits may indeed provide useful paleoclimatic data.

Climatic reconstructions may be drawn from the comparison of past and modern ranges of *Heterogaster urticae*, a bug mainly dependent on *Urtica dioica*, a very common nettle present everywhere in Britain. The nettlebug is now restricted to southern England but numerous fossil records from the first to sixteenth century (i.e., before the Little Ice Age) in northern England suggest that in this region temperatures were probably 1

or 2 °C higher than today (Kenward, 2004). The fossil occurrence in Roman sites of several other bugs (*Sehirus luctuosus*, *Syromastus rhombeus*, *Aphanus rolandri*), and also beetles (*Airaphilus elongatus*, *Heptaulacus sus*, *Heptaulacus testudinarius*, *Odacantha melanura*, *Plateumaris braccata*, *Bagous czwalinai*), to the north of their modern range, also suggest that temperatures during second to fourth century were 1 or 2 °C higher than today (Kenward, 2004). This corresponds with the Roman climate optimum. However, Holocene distribution shifts of semiaquatic Coleoptera should be interpreted with caution in terms of climate changes, since it is suggested by Andrieu-Ponel and Ponel (1999) that in the French region of Provence (and certainly elsewhere in Europe), the local extinction of fen species such as *Odacantha melanura* may have been a consequence of fen drainage and other human activities.

During the ninth to eleventh centuries, there is also a wealth of data from Heteroptera and Coleoptera supporting the hypothesis of summer temperatures higher than today by 1 or 2 °C (in agreement with the climate optimum around AD 1000): in northern England, examples of this include the presence of such species as *Eurydema oleracea*, *Coreus marginatus*, *Ischnodemus sabuleti* (Heteroptera), *Odacantha melanura*, *Cryptolestes duplicatus*, *Phymatodes testaceus*, *Pediacus dermestoides*, *Anthicus antherinus*, *Anthicus bifasciatus*, *Acritus homoeopathicus*, *Apion difficile*, several *Platysthetus* species, and *Xestobium rufovillosum* (Coleoptera).

There are few beetle records dated to the later Medieval and post Medieval period (Kenward, 2004), and therefore the effect of the Little Ice Age (roughly about AD 1450–1880) on insect ranges is still poorly documented. A recent review of this topic by Buckland and Wagner (2001) emphasizes the difficulty of extracting a climatic signal from beetle assemblages deposited in an environment increasingly perturbed by human activities and fragmentation of habitat, but it seems likely that some species were indeed affected by Little Ice Age cooling. These beetles became extinct in the northern parts of their range or even eradicated from Britain. This may be what happened to the beetles, *Airaphilus elongatus* (Osborne, 1997), *Gyrinus colymbus* (Girling, 1984), *Aphodius quadrimaculatus* (Osborne, 1969), *Xestobium rufovillosum*, *Odacantha melanura*, *Hydrophilus piceus* (Buckland and Dinnin, 1993) and the bug *Heterogaster urticae* (Kenward, 2004).

The present northward expansion of many insects may be interpreted as a consequence of a probable global warming that has taken place since the Little Ice Age. This has been particularly well documented for the Lepidoptera, but there is also evidence from many other insect orders, especially Heteroptera (Kenward, 2004). The discovery of several beetle species in southern France, well beyond their northern limit, may also be attributed to an increase in temperature. This is probably the case of the darkling beetles (Tenebrionidae) *Gonocephalum yelamosi* and *Pseudoseriscius pruinosis*, and the ground beetles *Paracelia simplex* and *Syntomus fuscomaculatus* (Ponel and Jeanne, 1997).

Impact of Forest Clearance on Saproxylophagous and Grassland Coleoptera

Again the overwhelming majority of data have been obtained from British sites, and a recent review of this issue was provided

by Whitehouse (2006). The impact of forest clearance on 'Urwald' insects (associated with old primeval forest) from the mid-Holocene onwards was perceived early in the history of Quaternary entomology, but more recent detailed studies have provided a very accurate picture of the profound changes that affected the beetle fauna in response to the progressive destruction by man of the natural oak and linden forest that dominated the British landscape from the early Holocene to about 5000 BP. Of particular interest is the site of Thorne Moors, thoroughly analyzed by Buckland (1979). This Bronze Age site, dated to about 3000 years BP, yielded a very rich Urwald beetle assemblage. This fauna included many saproxylophagous species now extinct in Britain, such as *Rhysodes sulcatus*, *Isorhipis melasoides*, *Prostomis mandibularis*, *Mycetina cruciata*, *Peltis grossa* (Figure 2), or with an extremely limited distribution in Britain, such as *Dryophthorus corticalis* or *Eucnemis capucina*. According to Whitehouse (2006), at least 40 beetle taxa found in Holocene deposits in Britain and 15 in Ireland are now apparently extinct in the British Isles, and this list is destined to expand in the future with the analysis of more sites (Buckland and Dinnin, 1993).

A similar pattern emerges from the study of continental sites, especially in France, since several records of Urwald beetles were obtained from seminatural archaeological contexts dated to about 5000 BP in the lacustrine village of Chalain (Ponel, unpublished data). Examples include *Peltis grossa*, *Lichenophanes varius*, *Bothrideres contractus*, and *Dryophthorus corticalis*. Unlike Britain, all these species are still present in France today; however, some of them (e.g., *Peltis grossa*) are now relegated to old-growth mountain forests, especially in the Pyrénées. This is probably because the steep slopes of their last strongholds have not been disturbed by human action.

Figure 2 *Peltis grossa* (Coleoptera: Trogositidae), a saproxylic beetle now extinct in Britain and associated with primeval forests.

Their inability to recolonize suitable habitats from such refuges may be a consequence of a low dispersal potential, but it is also possible that suitable old-growth forests are not available elsewhere in France.

Interestingly, the removal of the original forest cover did not affect only saproxylophagous beetles, but also other species not directly associated with woodland. This is probably the case for the water beetle *Agabus wasastjernae* found today in Scandinavian native pine forest where it lives in acid pools (Buckland, 1979) and almost eradicated from Britain along with the coniferous cover.

Wholesale forest clearance during the Neolithic period not only resulted in the retraction and eradication of saproxylophagous beetles but, as might be expected, it led also to the parallel expansion of open environment and grassland beetles. This faunal change is well documented in many British sites, particularly from the Bronze Age, and beetle assemblages from that time are progressively dominated by species associated with dung, such as the representatives of the large coprophagous genera *Onthophagus* and *Aphodius*, and the coprophilous rove beetles *Oxytelus* and *Platysthetus*. Many grass root feeders such as *Adelocera murina* and *Phyllopertha horticola* are also found in significant numbers. Such assemblages dominated by dung and grassland beetles suggest that grazing animals were abundant, in a predominantly open environment. Most of the studied sites show that beetle assemblages are almost totally devoid of tree-dependent species at that time and suggest an increasing representation of open environments in the British landscape, but it is probable that remnants of forests and extensive grasslands coexisted until the late Bronze Age (Osborne, 1978). During the Roman period the landscape in the British Isles was probably very similar to the present. In Southern France, the analysis of beetle assemblages sampled near the Rhône valley also suggests that the landscape was already completely open 2000 years ago and has remained so until now (Andrieu-Ponel et al., 2000).

More recently, Whitehouse and Smith (2010) have reanalyzed a range of British sites and beetle assemblages dating from the first half of the Holocene and a slightly different picture emerges from this synthesis: the proportion of beetle species indicative of open and forested environment is highly variable at the study sites, suggesting that open areas persisted and were locally important during the Mesolithic. The landscape at that time was probably a mosaic of woodlands and open clearings. Beetle assemblages from the later Mesolithic suggest a closing of the forest, although open environments were still present. The early Neolithic period is marked by an increased complexity of the landscape: dung beetles suggest a progressive opening whereas saproxylophagous beetles persist in a context of landscape heterogeneity and high regional variability. According to Whitehouse and Smith (2010), the low representation of the dung beetle community do not clearly suggest that open areas were a consequence of grazing activities of large herbivore herds, prior to the Neolithic period. In this context, it is worth noting that Smith et al. (2010) have shown from modern analog studies that the representation in fossil assemblages of tree-dependent beetles and dung beetles could be an indicator of openness of the landscape and presence of grazing mammals, but further analyses are required to precisely characterize this trend.

Other Consequences of Human Action

As indicated above, there is increasing evidence concerning the role of man, rather than that of climate, on the retraction of the range of hygrophilous or semiaquatic beetle species. This phenomenon has been described from the ancient marsh of Tourves (southern France) in a Holocene sequence spanning the Neolithic transition. At about 4310 BP a marked change is recorded by the beetles as a rich marshy fauna is suddenly replaced by an impoverished fauna in which running-water elements suggest a change in the hydrological regime; *Odocantha melanura* and *Cerapheles lateplagiatus* disappear from the assemblages. Both species are now restricted to Camargue, the last extensive marshy area in Provence, about 100 km westward (Andrieu-Ponel and Ponel, 1999). It is suggested that hydrologic changes were induced by drainage, associated with the intensification of cultivation practices in a region densely populated by Neolithic people.

The disappearance of riffle beetles (Elmidae) from rivers in Britain also seems to be attributed to forest clearance. These running-water beetles, adapted to highly oxygenated rivers, are found only on the gravelly bottom of streams, where they hang on the lower part of shingle by means of their oversized claws. It is likely that a secondary impact of the removal of the forest cover was an increase of soil erosion leading to a rise of alluviation processes in lowland areas, muddying the waters and thus making them unsuitable for Elmidae (Smith, 2000).

A further consequence of the development of agriculture is the range extension of opportunist beetle species now abundant in cultivated areas in Britain but unknown before Roman times. This is the case not only of the ground beetles *Pterostichus madidus* and *Zabrus tenebrioides*, but also of thermophilous species now very rarely found in the wild but usually associated with human habitations and livestock shelters, such as *Aglenus brunneus*, *Tenebroides mauritanicus*, *Oryzaephilus surinamensis*, and many others. The case of the dissemination of several species such as the grain weevil *Sitophilus granarius* is especially interesting since they are strictly associated with stored food products and are unable to live outside human habitations (Figure 3).

Figure 3 A beetle assemblage containing several synanthropic species from a Medieval archaeological site near the Vieux-Port of Marseille (France).

Their geographic origin remains obscure and it is likely that some of them originate from tropical regions, but this issue is still a matter of debate (Buckland, 1981).

Holocene History of the Beetle Fauna of Mediterranean Mountains

During the last 15 years, particular attention has been paid to the Holocene history of insect faunas in southern France and especially in the Mediterranean mountains (Southern Alps, Eastern Pyrénées). Coring of long continuous Holocene sequences was performed with either multiple coring techniques, or with large-volume corers (Figure 4), allowing sufficient quantities of sediment to be obtained. With such sampling procedures it is possible to obtain enough material to conduct multidisciplinary studies including, for example, Coleoptera, chironomids, pollen, and plant macrofossil analyses, leading to increased precision in the reconstruction of Human activities (such as pastoralism, agriculture, and mining) in mountains and in the reconstruction of past fluctuations of altitudinal treeline. A recent study by Ponel et al. (2011) at Lac des Lauzons in the Southern Alps illustrates this combined approach and provides an original insight into the forest history in this region, from the retreat of the ice sheet to the present.

In the Eastern Pyrénées, the key site of La Restanque, located at 1620 m above sea level, provides an excellent example of climatic and paleoenvironmental reconstructions based on a succession of Late Glacial–Holocene insect assemblages. A 5-cm resolution analysis of this 4 m profile yielded one of the most detailed (ongoing) analyses of the last 13 000 years. This record (Ponel et al., 2004) provides original data concerning climatic and environmental changes during the Late Glacial–Holocene transition. This history documents changes in insect faunas, in conjunction with vegetational changes, and human impact on the environment (Figure 5).

The lower part of the La Restanque insect sequence is characterized by the abundance of cold-adapted taxa, particularly of *Helophorus glacialis*, a beetle restricted to the margin of melting snow patches. This species lives at sea level in northern Scandinavia but well above 2000 m in southern Europe. It is

Figure 4 Large-diameter corer (ø 20 cm) used for sampling at La Restanque, French Pyrénées.

Figure 5 Succession of insect assemblages at La Restanque, French Pyrénées (1620 m), compared with pollen chronozones. The diagram shows the minimum number of individuals. Dq, isolated occurrence of the thermophilous ant *Dolichoderus quadripunctatus*. Preferred host plants of a selection of monophagous or oligophagous weevils: *Rhynchaenus fagi* associated with beech (*Fagus sylvatica*), *Rhynchaenus quercus* associated with oak (*Quercus*), *Anoplus plantaris* associated with birch (*Betula*), *Orobitis cyaneus* associated with violet (*Viola*), *Micrelus ericae* associated with heather (*Calluna vulgaris* and *Erica tetralix*).

a good climate indicator since it requires mean July temperatures below 10 °C to complete its life cycle. The dominance of this cold-adapted insect fauna clearly indicates that no forest cover was present at this time. This part of the sequence may be attributed to the Late Glacial interstadial, since it is likely that at such high altitudes the Late Glacial warming did not reach a sufficient level to allow warm-adapted insects to survive there, but allowed cold-adapted taxa to settle shortly after the Würmian deglaciation. Comparison with pollen analyses carried out on the same sequence confirms this reconstruction.

The perceptible rise in cold-adapted beetles in the next faunal unit suggests that this unit corresponds to the Younger Dryas. Immediately after this cold interval, at the onset of the Holocene, the disappearance of cold-adapted beetle species was dramatic, signaling the beginning of Holocene warming. This event is synchronous with a sharp peak of *Drusus discolor*, a caddisfly (Trichoptera) that lives today in cold and rapid mountain streams. This caddisfly is especially interesting since it suggests a short period of high-energy streams, certainly linked with large-scale snow melting induced by climatic

warming. In its turn this taxon disappears quickly, suggesting rapid environmental change, the disappearance of most of the snow cover and a concurrent decrease in stream velocities.

This initial warming phase was followed by a period characterized by regular occurrences of arboreal beetles. Beetles associated both with broadleaved and coniferous trees were present, suggesting that forest cover was established in the vicinity of the site. This period corresponds with the Boreal chronozone (9000–8000 BP). Surprisingly, few forest-dependent terrestrial beetles (associated with shaded environments) were identified, suggesting that the forest cover was not dense. At this period, temperatures much higher than today are indicated by several taxa, including the arboreal ant *Dolichoderus quadripunctatus*. This is a predominantly lowland species that is rather thermophilous and unable to live today at such high altitudes.

The next unit, between 8000 and 4700 BP, is marked by the disappearance of running-water beetles and by the rise of standing water and hygrophilous marshy species. This period corresponds with the Atlantic chronozone. It is possible that

these events could be related to changes in local hydrology, such as a shift from a fluvial regime to a lacustrine environment, associated with the infilling of the depression.

During the Subboreal (4700–2700 BP) and the Subatlantic (2700 BP onward), the human impact on the fauna and the forest cover is suggested by a complex sequence of events, including a decrease in conifer-dependent beetles, a reappearance of open environment beetles, and a peak of the carpenter ant, *Camponotus*. Most of the representatives of this genus are dependent on dead wood, since they dig galleries in old stumps and trunks to establish their nest. This peak of *Camponotus* is likely attributed to the increased availability of dead wood after forest clearance (fires, tree felling) and not to climatic influence, since no cold-adapted taxa are recorded at that time. Simultaneously, the beech forest became established nearby, as attested by the occurrences of the weevil *Rhynchaenus fagi* that feeds exclusively on beech. Another weevil, *Orobitis cyanea* that feeds exclusively on *Viola* in shaded underwoods, suggests that a true forest environment prevailed at this period. At that time it appears that the Restanque site was situated in an ecotone, at the boundary between a decimated conifer forest and an expanding beech forest. The uppermost samples of the sequence, corresponding to the end of the Subatlantic interval, are marked by an extremely impoverished insect fauna, partly for taphonomic reasons, but certainly also because heathlands expanded, at the expense of forests. This is suggested by the isolated occurrence of the beetle *Micrelus ericae*, a weevil dependent on heaths (Ericaceae).

Despite some possible events of local significance, it is likely that the broad pattern of faunal successions described at La Restanque is valid at a regional scale, and accurately reflects the progression of beetle assemblages and environments at high altitude regions in the eastern Pyrénées.

Conclusion

Beetle are recognized as excellent biological markers of ancient environments and they display a great sensitivity to climate change. The analysis of beetle fauna successions during the Postglacial period in Europe provides ample evidence for climate and environmental changes at the onset of the Holocene, and independent proxy data concerning the disruption of landscapes and vegetation under human activity (forest clearance, habitat fragmentation, agriculture, pastoralism) from the Neolithic period onwards. However, a detailed reconstruction of subtle Holocene climate evolution from beetle data is still not available, precisely because human action and climate-induced faunal changes during this period are extremely difficult to disentangle. A special effort devoted to this problem should be made in the future.

Introduction

The exoskeletal remains of beetles (Coleoptera) preserve well in waterlogged sediments of Pleistocene and Holocene age. Although the transition from the last glaciation to postglacial environments was a time-transgressive phenomenon, in most regions of North America this climatic transition took place between 14 000 and 11 550 years ago (12 000–10 000 ^{14}C yr BP). Most of the North American fossil beetle assemblages greater than 11 500 years in age are discussed in the article entitled 'late Pleistocene Beetle Records from North America.' In this article, I discuss the Late Glacial fossil beetle record of just the Maritime region of Canada, as well as Holocene records from across the continent.

In recent decades, studies of postglacial fossil beetle assemblages have been carried out in many regions of North America. [Table 1](#) lists 24 postglacial faunal sites from eastern and central North America, and [Table 2](#) lists 20 postglacial sites from western North America. This article reports on the major findings of these studies, in terms of paleoenvironmental reconstructions and shifting distribution patterns (biogeography) of the species found in the fossil assemblages, all of which remain extant today. Some of the fossil assemblages discussed here formed part of purely paleontological research projects. Others formed part of archaeological research, as noted in the text.

The paleotemperature estimates discussed are derived from the Mutual Climatic Range (MCR) method of paleoclimate analysis, as discussed in the Overview for this section. For sites in eastern and central North America, the MCR method was used to provide estimates of mean temperatures of the warmest (TMAX) and coldest (TMIN) months of the year. TMAX and TMIN estimates are discussed in terms of departures from the modern TMAX and TMIN of the study sites in question.

Research in Eastern North America

Fossil beetle assemblages of postglacial age have been studied in eastern Canada, New England, along the Mississippi drainage in the mid-western United States, and in the Canadian Territory of Nunavut ([Figure 1](#)). Many of these assemblages represent early postglacial environments ([Table 1](#), sites 1–14). Only a few mid-Holocene assemblages have been described from these regions ([Table 1](#), sites 15–18). Late Holocene assemblages, including three from archaeological sites, span the interval 3.5 to 0.1 ka ([Table 1](#), sites 19–24).

Late Pleistocene–Holocene Transition

The fossil beetle record from many parts of North America indicates a relatively smooth transition from glacial to

interglacial climates, beginning about 17 ka (calibrated years ago $\times$ 1000) ([Elias et al., 1996](#)). Throughout most of North America, paleotemperature reconstructions based on beetle assemblage data do not show a climatic reversal during the Late Glacial interval (17–11 ka). The one prominent exception to this comes from the Maritime region of Canada. [Miller and Elias \(2000\)](#) reconstructed mean July temperatures (TMAX) and mean January temperatures (TMIN) from radiocarbon-dated fossil beetle assemblages from a suite of late-glacial sites in this region. These assemblages date from 14.9 ka to 12.5 ka. In the Maritime region, multiple lines of evidence, including stratigraphy, palynology, chironomid fossils, and beetles, suggest a climatic deterioration during the Younger Dryas chronozone. MCR estimates suggest several 'events' in the regional fossil beetle record that appear similar to climate events recorded in the GRIP ice core record, including the Younger Dryas cooling event from GI-1a to GS-1, beginning ca. 12 650 GRIP yr BP. The results of MCR-based temperature reconstruction suggests a drop in TMAX of about 5 °C between 13 ka (at Brookside, Nova Scotia) and 12.5 ka (at West Mabou, Nova Scotia). These results compare well with the temperature reconstruction of summer surface waters based on chironomids ([Levesque et al., 1997](#); [Lotter et al., 1999](#)). The fact that there is little fossil beetle evidence for a Younger Dryas cooling event elsewhere in North America lends support for the paleoceanographic model ([Duplessy et al., 1996](#)) that links this cooling event with changes in circulation patterns in the North Atlantic. The only other North American region from which beetle records indicate a Younger Dryas cooling is arctic Alaska ([Elias, 2000](#)). However, few continuous series of beetle assemblages have been studied from this time interval in most regions of North America.

Most early postglacial beetle faunas from eastern and central North America are indicative of climatic regimes close to modern parameters ([Table 1](#)). The exceptions to this include sites that were located in close proximity to large bodies of glacial meltwater, such as Lockport Gulf, New York. Here, at 11.45 ka, TMAX was 1–4.5 °C colder than today ([Elias et al., 1996](#)). Climatic amelioration through the early Holocene is indicated by the mid-western beetle assemblages. [Schwert and Ashworth \(1988\)](#) discussed the discrepancy between early postglacial environments deduced from insect assemblages and paleobotanical reconstructions in the mid-western United States as follows. Pollen and plant macrofossils that accumulated in ice-marginal deposits just after deglaciation reflect tundra-like communities with sedges and *Dryas*, and are lacking trees and shrubs. However, the insect faunas are consistently different, being analogous to modern faunas from the middle of the boreal forest zone. At each study site, the discrepancy between the plant and insect evidence has been accounted for by invoking a substantial lag in the arrival and establishment of woody plants on deglaciated landscapes.

Figure 1 Map of eastern and central North America, showing location of fossil sites discussed in text. Site numbers match those in [Table 1](#).

As in central Europe, this lag may represent the time needed for ecological succession from open ground to herbaceous cover, shrub cover, and finally forest cover. The most recent paleobotanical reconstructions for the eastern and central United States (e.g., [Grimm and Jacobson, 2004](#)) suggest that such lags may have lasted for centuries, not for millennia. The paleoclimatic interpretations from the two disciplines (beetles and pollen) seem to be coming into closer agreement in recent years. For instance, a syntheses of palynological data ([Grimm and Jacobson, 2004](#)) concluded that “the climate of the Northeast was warmest and driest during the early Holocene ... from about 10 200–6000 cal yr BP—a time of enhanced summer insolation.” This conclusion agrees well with fossil beetle reconstructions.

[Elias \(1982\)](#), [Lavoie et al. \(1997\)](#), and [Lavoie and Arsenault \(2001\)](#) studied late Holocene beetle assemblages from sites near arctic treeline in northern Quebec and Labrador, Canada. Based on MCR analysis, [Lavoie et al. \(1997\)](#) found that summer temperatures in northern Quebec were 2.8–5.5 °C higher than modern from 6.7–1.9 ka. [Elias \(1982\)](#) found evidence of climatic cooling in northeastern Labrador from 2.7–0.9 ka. However, [Lavoie and Arsenault \(2001\)](#) found no evidence of cooling in the James Bay region during the last 5.7 ka. This suggests either that climates varied in different parts of Quebec–Labrador during the late Holocene, or that the northern tree-line faunas were more sensitive to small-scale changes than faunas that lived nearer the center of the boreal forest.

Environmental Archaeology Studies

One of the principal differences between European and North American postglacial environments has been the relatively

strong human influence on the landscapes of Europe during at least the last 5000 years, compared with the relatively weak human disturbance of many North American landscapes until at least late prehistoric times. The difficulties experienced by European researchers in disentangling the effects of human perturbation from the effects of climate change on postglacial beetle faunas (see [Postglacial Europe](#)) have not hindered North American workers to the same extent. The hunter-gatherer societies of the Americas did not clear forests and plant crops until the last few centuries.

Fossil beetle assemblages taken from archaeological sites in eastern and central North America have documented physical environments and human living conditions at several sites. Fossil insects were studied from disposal pits at Cahokia, Illinois ([Pauketat et al., 2002](#)). One of the aims of this study was to determine the timing of the disposal events represented by deposition of refuse in barrow pits. All but one of the studied deposits contained sizable quantities of insects active during the warm months between April and October. The fossil assemblages were dominated by beetles (58%), fly pupae (28%), and ants (14%). Some assemblages were indicative of rich mounds of discarded plant and animal wastes that were exposed for sufficient time, several days to several weeks, to allow insect colonization.

[Bain \(1998\)](#) studied beetle remains from a colonial-era archaeological site in Boston, Massachusetts. The fossil assemblages were extracted from sediments that accumulated in a latrine. Bain identified 42 beetle species, including 22 European taxa, and one that was possibly of Caribbean origin. Five beetle species in the fossil assemblage normally attack wood, suggesting that woodworking took place nearby, such as a sawmill, a furniture shop, house building, or stacks of

firewood. A large number of granary weevils (*Sitophilus granarius*) were found, indicating weevil infestation of stored grain or flour.

Bain's (2001) study of insects from the Îlot Hunt site in Quebec City, Canada indicates that the late nineteenth century was a time of great change in urban sanitary regulations and awareness of public health problems. Bain analyzed insect fossil samples from two latrines, a drain, and an abandoned well, representing both domestic and commercial establishments.

Research in Western North America

Postglacial sites in western North America include eight sites in the Rocky Mountain region (Table 2, sites 1–8) and twelve sites in the arid southwest (Table 2, sites 9–20). The Rocky Mountain sites represent organic deposits sampled from lake sediments, peat bogs, and one cave deposit (Rat's Nest Cave, Alberta). The southwestern sites are all woodrat middens.

Studies in the Rocky Mountains

In many ways, the Rocky Mountain region is ideally suited for Quaternary insect studies. The vertical relief of the mountain chain has provided regional biota with a wide variety of physical environments, expressed in the development of ecological communities ranging from grasslands in the eastern foothills zone through several types of montane and subalpine forest communities, to the alpine tundra at or near mountaintops. Furthermore, the ecotones, or boundaries, between these communities have undergone noticeable shifts in elevation in the late Quaternary, facilitating the study of environmental change, as a given site documents different biological communities through time.

Fossil insects from the Rocky Mountains have left us important records of past events and biotic responses. The atmospheric moisture caught by the Rockies makes this mountain chain wetter than the adjacent plains, and this in turn has led to the accumulation and preservation of organic deposits.

Rocky Mountain study sites (Figure 2) span an elevational range from the foothills zone to the Alpine tundra. The general trend in regional faunas was that cold-adapted species lived at high elevations during the postglacial warm interval, but during the last glaciation, these beetles shifted their ranges downslope by 300–1500 m (Short and Elias, 1987; Elias and Toolin, 1989).

MCR analysis of fossil beetle assemblages from the Rockies indicates that following deglaciation, postglacial summer warming was rapid. This is indicated by an assemblage dating 16.2 ka, with TMAX only 2.1 °C cooler than modern. By 11.6 ka, several assemblages indicate warmer than modern TMAX and TMIN values. Pollen evidence suggests that coniferous forests did not reach their modern elevations until about 10 ka, more than 1000 years after climatic amelioration had reached modern levels, based on the beetle evidence. By that time, beetle MCR reconstructions indicate that both summer and winter temperatures were already beginning to decline from early postglacial maxima.

Figure 2 Map of western North America, showing location of fossil sites discussed in text. Site numbers match those in Table 2.

TMAX values remained above modern levels and TMIN values remained below modern levels until about 3.2 ka. These long-term trends were followed by a series of small-scale oscillations in the late Holocene. Pollen spectra from sites in the Colorado Front Range show substantial changes after 3.8 ka, interpreted as either a lowering of treeline, or a thinning of subalpine forests, or both (Short, 1985). Pine pollen also became less abundant in subalpine pollen spectra at this time. These changes were inferred to be a response by the vegetation to climatic cooling.

The site of Rat's Nest Cave in Alberta yielded organic detritus that accumulated at the bottom of a deep natural shaft inside the mouth of a cave (Bain et al., 1997). The beetle faunas span the last 2000 years, and their composition suggests environmental conditions similar to modern parameters at the site. This is in contrast to beetle assemblages from this interval from farther south, in the Central Rocky Mountains. The latter are indicative of a series of climatic oscillations during this time, with a relatively warm period about 1 ka, followed by a relatively cold period in the last 500 years.

Biogeography of the Rocky Mountain Beetle Fauna

Because of the persistently cold climates at high elevations, the Rockies have been a refuge for many cold-adapted species of

both plants and animals, even during the warmest interglacial intervals. Species that shifted southward in front of glacial ice advances in the interior of North America had only two options for survival when the climate began warming and the ice receded at the end of the last glaciation. They had to migrate either northward or up the slopes of mountains, in search of suitably cold climate. Thus, cold-adapted beetles that lived on the plains south of Denver toward the end of the last glaciation have retreated to the Alpine tundra in the Colorado Front Range (Elias, 1986). In contrast to the Rocky Mountain fauna, cold-adapted species living in the central Great Plains region were not able to migrate north at the end of the last glaciation. At that time, climatic warming caused the extirpation (regional extinction) of much of the cold-adapted beetle fauna in this region, with small populations of Arctic and subArctic species surviving in Alpine habitats of the Cordillera and Appalachians, or in short-lived habitats associated with stagnant ice (Schwert and Ashworth, 1988).

There have been a number of regional extirpations from the Rocky Mountain beetle fauna during the last 17 ka, probably as a result of large-scale climatic change (Figure 3). Six of the eight species extirpated before the Holocene have shifted their distributions to the north. These are all cold-adapted animals, either Arctic or boreo-Arctic species. The most extreme displacement of distribution is that of a rove beetle (Staphylinidae), *Holoboreaphilus nordenskiöldi*, which lives today in Arctic Canada, 3000 km north of its Late Glacial locality at Marias Pass, Montana (Figure 2). Two additional species made their last Rocky Mountain appearance in an assemblage from Marias Pass, dated at just over 13.3 ka. These are a ground beetle (Carabidae), *Bembidion sulcipenne hyperboroides*, and a carrion beetle (Silphidae), *Thanatophilus trituberculatus*. *B. sulcipenne hyperboroides* is a northwestern North American species, living today in northern British Columbia, the Yukon Territory, and Alaska. *T. trituberculatus* is a northern, cold-adapted carrion-feeder, which probably also feeds on other insects inhabiting carrion. Its modern range extends north to the Arctic in Canada

and Alaska, but its southern limit does not reach the lower 48 states of the United States.

Two species make their last appearance in the Rocky Mountain fossil record at approximately 14.7 ka, from the Mary Jane site in Colorado. One of these is the water scavenger beetle (Hydrophilidae), *Helophorus splendidus*. This beetle is found today in the northern Holarctic regions, including northeastern Siberia and the arctic coast of the Canadian Northwest Territories. It was found also in the 17.8 ka-assemblage from Lamb Spring, and is indicative of tundra conditions at this site.

The Huntington Canyon site, in the subalpine zone of the Wasatch Mountains of Utah, yielded one species that has been regionally extirpated. The assemblage dates to 13.2 ka. *Bembidion gordonii* is a riparian ground beetle that lives on the banks of fast-running mountain streams. Today, however, its distribution is restricted to the mountains of the Pacific Northwest, from British Columbia to Oregon. Based solely on its modern distribution, a biogeographer might describe *B. gordonii* as endemic to the Pacific Northwest, but the Huntington fossil record demonstrates that it was more widespread in the recent past (i.e., 'recent' in terms of the longevity of the species).

Of the species extirpated during the Holocene, only one has shifted its distribution to the north. The riparian ground beetle, *Bembidion rusticum*, now lives only in British Columbia and northward, a distance of more than 2600 km from Lake Emma, Colorado, where it was found as an early Holocene fossil. Lake Emma also yielded *Bembidion sierricola*, which is restricted today to the mountains of the Pacific Northwest, from California to southern British Columbia (Lindroth, 1963). The dung beetle (Scarabaeidae) *Dialytes ulkei*, was extirpated from the Rockies sometime after 9600 yr BP. Its last occurrence in the regional fossil record was at La Poudre Pass, Colorado (Figure 2). *D. ulkei* is an eastern North American species today, ranging from southern Quebec, southward in the Appalachian Mountain chain to South Carolina. Finally, the ground beetle, *Selenophorus gagatinus*, was last recorded from Colorado in a

Figure 3 Last recorded fossil occurrence of various beetle species in Rocky Mountain region postglacial fossil assemblages. After Elias, 1981.

2400 yr BP assemblage from the Roaring River, in Rocky Mountain National Park (Figure 2). Today *S. gagatinus* is an eastern North American species, ranging as far west as Indiana. In the late Quaternary interval, it was widespread in western North America, as it was also found in ancient packrat middens from the northern Chihuahuan Desert (Figure 4), in assemblages ranging from 24 to 4.7 ka (Elias and Van Devender, 1990).

Based on the fossil evidence discussed above, it is clear that the current biological communities of the Rocky Mountain region developed only since the end of the last glaciation. They are the product of changing Quaternary environments. Changes in distribution have been large-scale and rapid. These changes demonstrate the great mobility of many beetle species, and their ability to move great distances in order to satisfy their ecological requirements in the face of changing climates. These changes also suggest that the current insect communities of the Rocky Mountain region are simply the latest reshuffling of

species, and that species composition is probably in a more or less continuous state of flux (Elias, 1991).

Since the 1980s, insect fossils from packrat middens have received intensive study. Fossil insect research has been done in the Sonoran Desert and the Great Basin, but the most intensively studied region (191 midden insect fossil samples from 27 sites) is the Chihuahuan Desert (Elias and Van Devender, 1990, 1992; Elias et al., 1995). The fossil insect assemblages from the southern Chihuahuan Desert in Mexico contain mixtures of desert- and temperate-zone species (Figure 4) in almost every interval from the Late Glacial through to the late Holocene. Midden assemblages from locations farther north in the Chihuahuan Desert are generally separated into glacial-age faunas with temperate-zone affinities and postglacial faunas with desert-zone affinities. The 'no modern analog' faunal assemblages indicate that the late Quaternary environments in this region were unlike any that exist today. After 14 ka, most temperate-zone beetle species in the central and northern

Figure 4 Scanning electron micrographs of fossil beetles from Chihuahuan Desert packrat midden assemblages. regions of the Chihuahuan Desert were replaced by either desert species or by more cosmopolitan taxa. The faunal change suggests a climatic shift from cool, moist conditions of Wisconsin glacial times to hotter, drier conditions in the early Holocene.

In the northern Chihuahuan Desert, woodland environments persisted until 13 ka, but the insect data suggest considerable open ground, with grasses at least locally important at the midden sites. The transition from the temperate (glacial) fauna to the more xeric postglacial fauna started by 14.7 ka. The timing of this faunal change was essentially synchronous throughout the northern Chihuahuan Desert. A major difference between the Big Bend and northern Chihuahuan Desert scenarios is the nature of this faunal change. In the Big Bend region, the transition was characterized by the disappearance of nearly all temperate species at about 14 ka. However, the xeric-adapted fauna did not appear in the Big Bend records until about 8.4 ka. In the northern Chihuahuan Desert assemblages, the xeric species first appeared at 14.7 ka, and several of the temperate grassland species that had lived there during the last glaciation persisted well into the Holocene. This mixture of xeric and temperate elements makes ecological sense, because these northern faunas were living close to the edge of the Chihuahuan Desert. The gradual shifting of northern desert boundaries in the Holocene probably created many marginal habitats for temperate species. By about 8.4 ka, the dominance of xeric species indicates establishment of desert environments, including desert grasslands, throughout the Chihuahuan Desert region. After 2.6 ka, the last of the temperate species was replaced by species associated with desert-scrub communities.

Work on late Quaternary insect faunas from the Colorado Plateau region (Elias et al., 1992) suggests that late Wisconsin climatic conditions were cooler and moister than present, and that the plateau supported a mosaic of grassland and shrub communities without modern analog. The temporal and spatial coverage of midden sites is relatively poor for this enormous region, especially in comparison with the work done on middens from the Chihuahuan Desert. However, it is possible to say that the transition from glacial to postglacial climatic regimes took place after 17 ka. Paleobotanical data suggest that major regional warming was well underway by 13 ka (Cole, 1990). The fossil insect data indicate that the most arid conditions in the Great Basin region occurred within the last 1500 years.

Insect faunas have also been studied from several sites in the Sonoran Desert (Hall et al., 1989, 1990; Clark and Sankey, 1999). Unlike the Chihuahuan Desert insect fauna, the Sonoran Desert fauna indicates little change from the late Pleistocene through to modern times. All taxa found in the Sonoran middens probably live within a few kilometers of the midden sites today. The Sonoran arthropod fauna showed a marked increase in diversity during the late Holocene, as more subtropical plants and warmer climates became established about 4.5 ka. Many warm-adapted beetles probably dispersed into southern Arizona from Sonora, Mexico, during the last 4 kyr. The increase in diversity in fossil arthropod assemblages has been correlated with the frequency of winter freezes, and secondarily with the amount of summer precipitation. This late Holocene peak in species richness is in sharp contrast to the

Chihuahuan Desert insect record, which showed the least number of species in late Holocene samples. If the Sonoran Desert insect fauna truly was stable through the late Quaternary, then this represents a significant difference between the Sonoran and Chihuahuan desert insect faunal histories.

On the whole, the results of North American postglacial beetle studies tend to agree well with reconstructions based on other proxy data, such as pollen and plant macrofossils. The only important discrepancies concern early postglacial environments. The fossil beetle records of all studied North American regions show unequivocally that at least summer temperatures reached modern levels very early in the postglacial period. Warm-adapted beetles were colonizing the recently deglaciated landscapes in the midwest and the Rockies, providing evidence of this warming, even though low herbaceous vegetation persisted in these regions for up to 1000 years after deglaciation. Likewise, in the Chihuahuan Desert, the shift from cool-temperate to warm-xeric beetle faunas anticipated the major changes in regional vegetation (notably, the upslope shift in lower treelines) by up to 1000 years (Elias and Van Devender, 1992). The rapidity and magnitude of postglacial warming identified in the fossil beetle records from both North America and Europe has been verified by rapid changes seen in oxygen isotope ratios of Greenland ice cores (Dansgaard et al., 1989).

Concepts in Stable Isotope Geochemistry

The light elements oxygen (O), hydrogen (H), carbon (C), and nitrogen (N) have two or more stable isotopes whose relative abundances vary slightly in nature. Since the early 1950s, geochemists have used isotopic variations in sedimentary materials to reconstruct past changes in climate. [Emiliani \(1955\)](#) first showed cyclical variations in the $^{18}\text{O}/^{16}\text{O}$ ratios of Foraminifera from deep-sea sediments on a 10^5 year timescale. He inferred that these changes reflected cyclical advances and

retreats of continental ice sheets causing coupled changes in both the temperature and $^{18}\text{O}/^{16}\text{O}$ ratio of seawater. While some of the best-known and most continuous isotopic records of Quaternary paleoclimate are arguably from deep-sea sediments ([Shackleton and Opdyke, 1973](#)) and continental ice cores, isotopic records from continental loci also provide important archives of past climate change.

The physical principles behind the use of isotope records can be summarized as follows. When a material is forming either as a result of chemical precipitation or biological activity,

the isotope ratios of the constituent atoms can reflect the temperature of the depositional process. As well, the isotope ratio of the newly formed material reflects the ratio in the medium from which it is formed (usually water) and this in turn can be controlled by climate change. When crystals of calcium carbonate (CaCO_3 ; calcite or aragonite) precipitate at equilibrium, their $^{18}\text{O}/^{16}\text{O}$ ratio is offset from that of the aqueous medium by a fractionation factor $\alpha_{\text{ct-w}}$ that depends on temperature, generally decreasing (causing $^{18}\text{O}/^{16}\text{O}$ of calcite to increase) by $\sim 0.24\text{‰}/^\circ\text{C}$. Likewise, the $^{18}\text{O}/^{16}\text{O}$ and deuterium/hydrogen (D/H) ratios of meteoric precipitation increase with temperature (by $\sim 0.7\text{‰}/^\circ\text{C}$ for $^{18}\text{O}/^{16}\text{O}$) except in the tropics where $^{18}\text{O}/^{16}\text{O}$ is a decreasing function of the amount of precipitation. Isotopes in surface waters derived from rain and snow-melt will likewise reflect changes in average temperature and rainfall. The $^{18}\text{O}/^{16}\text{O}$ ratios of minerals precipitated from water (including apatite in bones and teeth) reflect the ratio in environmental water.

Isotope ratios are reported using the delta (δ) notation. For example:

$$\delta^{13}\text{C} = \{[(^{13}\text{C}/^{12}\text{C})_{\text{sample}} / (^{13}\text{C}/^{12}\text{C})_{\text{std}}] - 1\} \times 1000$$

where 'std' is the standard: VPDB for $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ in calcite, VSMOW for $\delta^{18}\text{O}$ in water, and for δD (derived from $^2\text{H}/^1\text{H} \equiv \text{D}/\text{H}$).

There is a relative paucity of continuously deposited Quaternary sediments from which to extract stable isotopic records in the terrestrial realm compared to the marine record. Most terrestrial isotopic records for this period relate to specific, short-lived sedimentary loci or to collective records of disparate events such as soil profiles. The sections of the Encyclopedia on this topic largely present methodological treatments of the use of isotopes in paleoclimate rather than summarizing detailed climatic records (except for the Holocene, for which quasi-continuous records are more common). The highlights of these sections are summarized below.

Speleothems

Some of the longest, most accurately dated, and continuous isotopic terrestrial isotopic records are taken from deposits of CaCO_3 formed in caves, principally stalagmites and horizontally laminated flowstone. These deposits form as a result of supersaturation of calcium-rich solutions dripping from the cave roof. When deposited deep inside poorly ventilated caves, they can be formed in O isotopic equilibrium with drip water and therefore have the potential to record paleotemperatures. Drip waters isotopically resemble average meteoric precipitation above the cave; therefore $\delta^{18}\text{O}$ of the calcite ($\delta^{18}\text{O}_{\text{ct}}$) depends on both $\delta^{18}\text{O}$ of precipitation (controlled by temperature and rainfall amount) as well as the fractionation between calcite and water, $\alpha_{\text{ct-w}}$. The net effect can be either an increase or a decrease in $\delta^{18}\text{O}_{\text{ct}}$ with increasing atmospheric T (both are observed). Serial records drilled out of speleothems have been used to reconstruct the history of local and regional climate. Their precise U-series chronologies allow correlation with isotopic records in ice and ocean cores. Variation in $\delta^{13}\text{C}_{\text{ct}}$

records changes in organic activity above the cave including changes in amount of C_3 and C_4 plants.

Absolute temperatures of formation of speleothem calcite may be obtainable by analysis of fluid inclusions in the speleothem which represent trapped samples of original drip water. While the $^{18}\text{O}/^{16}\text{O}$ ratio may have changed due to post-trapping exchange, the D/H ratio of the included water can be used to reconstruct initial $\delta^{18}\text{O}$ using the meteoric water relationship $\delta\text{D} = 8 \delta^{18}\text{O} + \delta_o$ where $\delta_o \sim 10\text{‰}$. Thus, speleothems have the potential to provide archives of surface temperatures over the last 0.4 million years (My).

Teeth and Bones

The teeth and bones of mammals consist of hydroxyapatite (HA) and collagen. They contain records of isotopes of O and C (in HA) and C and N (in collagen). The $^{18}\text{O}/^{16}\text{O}$ of HA is mainly determined by the $^{18}\text{O}/^{16}\text{O}$ of consumed water including leaf water (for herbivores). $\delta^{18}\text{O}$ of HA reflects temperature change as it affects $\delta^{18}\text{O}$ in precipitation, and also relative humidity (RH) which causes leaf water to increase in ^{18}O . Serial sections of enamel in single teeth record seasonal changes in temperature or rainfall amount, while HA in bone (which is continuously remodeled) records long-term average climate.

The C and N isotopic records of bone have also been shown to vary with climate. In arid-to-semiarid zones, $\delta^{15}\text{N}$ increases with decreasing rainfall (Heaton et al., 1986) while $\delta^{13}\text{C}$ can increase as RH falls, due both to change in water balance and to increase in the proportion of C_4 plants in the diet.

Bones and teeth represent a highly discontinuous isotopic record, because they do not generally occur in long stratified sequences. An exception is at archaeological sites in Eurasia and Africa where more or less continuous sequences can be assembled from faunal remains at these sites.

Biogenic Carbonates

The shells of mollusks and other CaCO_3 -precipitating fauna are formed approximately in O isotopic equilibrium with the water in which they live. Therefore their $\delta^{18}\text{O}$ values reflect the temperature of deposition, partly because of the temperature-dependence of $\alpha_{\text{ct-w}}$ which decreases by $0.24\text{‰}/^\circ\text{C}$ and also because the $\delta^{18}\text{O}$ of the meteoric source of most surficial waters increases by ca. $0.7\text{‰}/^\circ\text{C}$. In larger lakes and rivers $\delta^{18}\text{O}$ of water is less variable and the effect of temperature on $\alpha_{\text{ct-w}}$ is dominant. There may be a *vital effect* leading to an offset of $\delta^{18}\text{O}$ from equilibrium, but usually the T-slope remains close to $-0.24\text{‰}/^\circ\text{C}$. Seasonal changes in $\delta^{18}\text{O}_{\text{ct}}$ of shells are recorded in annual layers of the shells and can be used to reconstruct seasonality. $\delta^{13}\text{C}$ values of these shells mainly reflect the $\delta^{13}\text{C}$ of dissolved inorganic carbon (DIC) in the water mass. This in turn is influenced by photosynthetic activity (which raises $\delta^{13}\text{C}$ of DIC). The $\delta^{18}\text{O}_{\text{ct}}$ of terrestrial snail shells is controlled by the $\delta^{18}\text{O}$ of water in the leaves of the snail's diet, and mainly reflects changes in RH (Goodfriend et al., 1989) while $\delta^{13}\text{C}$ reflects that of the leafy diet (Goodfriend, 1990).

The aragonitic otoliths of fish are also precipitated in O isotopic equilibrium while $\delta^{13}\text{C}$ reflects DIC of blood; the

latter is controlled by metabolic activity which can change with age and also with the level of activity of the fish.

Long sequential isotopic records of fossil shells in terrestrial sequences are rare due to the lack of extensive exposures of lacustrine sediments, but these can be used effectively to monitor past climate change. Aragonitic ostracod tests have also been used for this purpose in proglacial lake sediments (Schwarcz and Eyles, 1991).

Lacustrine Sediments

In addition to the shells that are enclosed in these sediments, part or most of the sediment itself may consist of chemically or biochemically precipitated CaCO_3 in the form of marl. The $\delta^{18}\text{O}$ of these sediments (generally formed close to isotopic equilibrium) varies in response to temperature, but may also reflect RH in evaporative lakes. Carbon isotopes are controlled by $\delta^{13}\text{C}$ of DIC, and strongly reflect changes in photosynthetic activity in the lake.

Nonlacustrine Terrestrial Carbonates

CaCO_3 is deposited in some arid-region soils as a result of evaporation of Ca-rich water in the soil in the presence of biogenic carbon dioxide (CO_2) and bicarbonate (HCO_3^-). The $\delta^{18}\text{O}$ of these carbonates is strongly influenced by evaporative enrichment of the soil water in ^{18}O with the result that there is no simple relation between $\delta^{18}\text{O}_{\text{ct}}$ and temperature. A regional trend with a slope of $+0.4\text{‰}/^\circ\text{C}$ is observed for soils experiencing low evaporation, close to the value expected for the balance between the meteoric water and $\alpha_{\text{ct-w}}$ effects discussed above.

Diffusive loss of soil CO_2 to the atmosphere leads to a dependence of $\delta^{13}\text{C}$ in soil carbonates on partial pressure of CO_2 in the atmosphere. More important for Quaternary soils, $\delta^{13}\text{C}_{\text{ct}}$ reflects the balance between C_3 and C_4 plants growing on the soil. Because of the preference of C_4 plants for warm, dry climate, this allows us to use variations in $\delta^{13}\text{C}_{\text{ct}}$ in stacked sequences of paleosols as an archive of paleoclimate.

A unique terrestrial carbonate deposit, which could also be considered a speleothem, is the buildup of calcite on the walls of Devil's Hole, a warm spring in Nevada, USA (Winograd et al., 1992). A well-dated record of secular variation in $\delta^{18}\text{O}$ resembles in many precise details the corresponding $\delta^{18}\text{O}$ record for deep-sea Foraminifera. There is, however, a striking offset in the ages of terminations (interglacial-glacial transitions) between the U-series-dated Devil's Hole deposits and the astronomically dated marine record. This discrepancy remains unresolved.

Terrestrial Organic Materials

Plant remains are found in terrestrial sediments both as organic rich peaty deposits and as traces of plant materials in

detrital sediments. Photosynthates (largely cellulose) are significantly depleted in ^{13}C with respect to atmospheric CO_2 as a result of multistage isotopic fractionations in leaves. The degree of depletion varies as a result of change in stomatal opening and is therefore an indicator of water availability. O and H isotopes reflect both the respective isotope ratios in meteoric water (and soil or ground water derived from it), as well as evaporative effects in leaves that enrich leaf-water in heavy isotopes. Thus, a combination of C, O, and H analyses of plant materials can provide a complex image of climatic change.

Serial samples of tree rings provide the most widely cited continuous isotopic records of plant materials. Peat deposits can provide sequences of organic matter mainly derived from mosses. Advances in mass spectrometry have opened up the possibility of isotopic analysis of pollen grains which form a minor component of many terrestrial sediments.

Conclusions

In general, stable isotope ratios in terrestrial materials are affected to approximately equal extents by two or more environmental parameters (including temperature, RH, rainfall, and $\delta^{18}\text{O}$ of meteoric or surface water). It is seldom possible to give a simple and unambiguous interpretation of a serial isotopic record in a sedimentary sequence. Nevertheless, the conflation of multiple isotopic indicators, sometimes from the same material (using different isotopes) can narrow down the possible interpretations assignable to a given series of wiggles on an isotopic graph. Our ability to analyze successively smaller samples opens up the possibility of extracting individual biomolecules for analysis, as well as higher spatial resolution in analyses of serial samples from single deposits such as speleothems or shells.

Speleothems are crystalline deposits of calcium carbonate (CaCO_3) formed in karstic caves as a result of precipitation from dilute aqueous solutions entering the cave, typically as drips from the roof. Karstic caves (q.v.) are formed by dissolution of soluble bedrock, usually a carbonate rock, by the action of meteoric water percolating from overlying soil or bedrock surfaces. This is partly due to organic activity in the soil that generates carbonic acid, which reacts with calcite or dolomite. Karstic dissolution forms cavities varying in size from less than 1 mm to passages many kilometers in length and tens of meters high (Ford and Williams, 1989). Karst can form in other kinds of rock (e.g., evaporitic sulfates), and speleothems can be formed of minerals other than CaCO_3 . However, this article will deal only with Ca carbonates.

Speleothems can be seen forming today and we can infer that some have formed throughout the Quaternary epoch. They occur in many geometric forms, including stalagmites (which grow upward from the floor of caves beneath a drip site), stalactites (growing downward from the roof of a cave), and flowstone—sheet-like horizontally or inclined layers of calcite produced where water from one or more sources has spread as a film across a cave floor or wall (Figure 1). When viewed in cross section (axially or longitudinally), many speleothems display a prominent laminated structure (Figure 2). These preserve records of secular variation in the properties of the speleothem material that can be interpreted as changes in conditions of deposition in the cave and thus, indirectly, on the Earth's surface above. These properties include the following:

- Chronometric age and rate of growth
- Isotopic composition of the CaCO_3
- Abundance and isotopic composition of fluid inclusions of water trapped during growth
- Trace element concentrations in CaCO_3
- Abundance and composition of organic impurities (especially humic substances)
- Mineralogy (calcite, aragonite, etc.)

Here, we focus on the first three items.

Stable Isotope Systematics in Speleothems

Before percolating through the bedrock, surface water is exposed first to atmospheric CO_2 and then to soil gases enriched in biogenic CO_2 . As water percolates through the bedrock overlying a cave, it can react extensively with the rock or may pass through with relatively little chemical interaction, depending on the nature of the openings through which it passes. Under conditions of diffuse flow through relatively tight fractures and joints, the water can approach chemical and isotopic equilibrium with the rock, whereas in larger, open channels entering caves, surface water may enter essentially unchanged.

On entering the cave, drip waters can begin to precipitate CaCO_3 as a result of two discrete processes: evaporation, which increases the concentration (activity) of Ca ions until the solubility of CaCO_3 is exceeded, and outgassing of CO_2 from the water, which results in the slow precipitation of CaCO_3 :

CaCO_3 potentially contains a number of distinct isotopic signals, recorded as variations in the relative abundance of the isotopes of Ca, O, and C. Only the latter two have been extensively studied.

Oxygen Isotopes

Variations in the $^{18}\text{O}/^{16}\text{O}$ ratio in water and O-bearing minerals have been widely used as proxies for various environmental records, especially temperature. CaCO_3 can isotopically exchange with water:

Epstein et al. (1953) showed that the equilibrium constant for this reaction, $K_{\text{ct-w}} = (^{18}\text{O}/^{16}\text{O})_{\text{ct}} / (^{18}\text{O}/^{16}\text{O})_{\text{H}_2\text{O}}$, depended only on temperature. Therefore, if a sample of CaCO_3 had precipitated in isotopic equilibrium with water of known $^{18}\text{O}/^{16}\text{O}$ ratio, we could determine the temperature of precipitation. Hendy (1971) showed that under conditions widely encountered in deep caves, speleothems formed at oxygen isotopic equilibrium with drip waters. This happened if the mode of deposition was by relatively slow outgassing of CO_2 from the drip water, whereas evaporative deposition (or rapid outgassing) led to disequilibrium precipitation. That is, under the latter conditions the oxygen isotope fractionation was not equal to the equilibrium constant at the temperature of deposition, and deviation from equilibrium increased as drip water traversed the surface of the speleothem. Hendy showed that the calcite precipitated along this path became progressively enriched in ^{18}O . Therefore, a convenient test for equilibrium was to measure the $^{18}\text{O}/^{16}\text{O}$ ratio of calcite along several points spaced some centimeters apart on a single growth layer. For equilibrium deposits it was expected that $(^{18}\text{O}/^{16}\text{O})_{\text{ct}}$ would remain constant, whereas disequilibrium growth layers would display (1) continuously varying $^{18}\text{O}/^{16}\text{O}$ and (2) a correlation between $^{18}\text{O}/^{16}\text{O}$ and $^{13}\text{C}/^{12}\text{C}$. The latter reflects the fact that rapid outgassing or evaporation were usually coupled with variations in the $^{13}\text{C}/^{12}\text{C}$ ratio of dissolved inorganic carbon (DIC) in the drip water. Speleothems satisfying the criteria of equilibrium deposition are invariably found deep inside long caves (>1 km) or in recently opened, formerly sealed cavities, where relative humidity was ~100% and where lack of significant movement of air resulted in high partial pressure of CO_2 with the result that outgassing of drip water was slow. Recent

Figure 1 Typical forms of speleothems: (a) stalagmites (middle stalagmite is ~40 cm high); (b) stalactite, ~4 cm in diameter at top, flanked by 'soda straws'; (c) thin stalactites (soda straws), ~5 mm in diameter, showing drip water emerging; and (d) flowstone, ~1 m wide. Photos by P. Beddows.

studies (Mickler et al., 2004) suggest that kinetic effects may prevent the attainment of isotopic equilibrium between calcite and water. However, actively growing stalactites ('soda straws') from deep, high-humidity caves have been shown by other authors to yield isotopic temperatures similar to the temperature in the cave.

The discovery of this means of recognizing speleothems deposited at equilibrium opened up the possibility of using $(^{18}\text{O}/^{16}\text{O})_{\text{ct}}$ variations in speleothems as a paleothermometer. Far from the entrances to most caves (>100–500 m), the temperature remains constant seasonally and approaches the mean annual surface temperature above the cave. Therefore, a

paleotemperature record from an equilibrium speleothem would provide a record of past temperatures on the surface for the duration of growth of the speleothem.

For a given sample of calcite extracted from such an equilibrium deposit, the temperature is given by the paleotemperature equation (Epstein et al. 1953):

$$T(^{\circ}\text{C}) = 16.5 - 4.3(\delta^{18}\text{O}_{\text{ct}} - \delta^{18}\text{O}_{\text{w}}) + 0.14(\delta^{18}\text{O}_{\text{ct}} - \delta^{18}\text{O}_{\text{w}})^2 \quad [3]$$

where $\delta^{18}\text{O}_x$ is defined as

$$\delta^{18}\text{O} = \left\{ \left[(^{18}\text{O}/^{16}\text{O})_x / (^{18}\text{O}/^{16}\text{O})_{\text{std}} \right] - 1 \right\} \times 1000 \quad [4]$$

Figure 2 Section through a stalagmite showing laminated structures (growth layers). Lighter zones are richer in fluid inclusions; note the detritus-rich layer at base. The color is due to the presence of humic matter in calcite.

where w is drip water, and std refers to one of the two international standards for $^{18}\text{O}/^{16}\text{O}$ ratios: Vienna Pee Dee Belemnite (VPDB) or Vienna Standard Mean Ocean Water. The units of $\delta^{18}\text{O}$ are ‰ (per mil). The precision of analyses of $\delta^{18}\text{O}$ is typically approximately $\pm 0.1\text{‰}$. Note, however, that in order to determine T , it is necessary to have values for $\delta^{18}\text{O}$ of both the calcite and the water from which it was precipitated.

$\delta^{18}\text{O}_{\text{ct}}$ is usually determined by reacting samples $\geq 100\text{ }\mu\text{g}$ with 100% phosphoric acid and analyzing the resultant CO_2 on a gas-source, isotope ratio-detecting mass spectrometer. Most studies of long-term variation in $\delta^{18}\text{O}_{\text{ct}}$ of speleothems have been done on stalagmites using axial sections (Figure 3) oriented more or less in a diametric section of the stalagmite. Samples are drilled out of the polished surface of the section. High-resolution records (with micrometer spacing) have been obtained using computer-driven milling machines (Mangini et al., 2005) and laser heating to decompose CaCO_3 to $\text{CaO} + \text{CO}_2$ (McDermott et al., 2001). In most studies of secular variation in $\delta^{18}\text{O}_{\text{ct}}$, the authors use the so-called Hendy test to ensure that the deposits were formed in oxygen isotopic equilibrium, reporting $\delta^{18}\text{O}_{\text{ct}}$ and $\delta^{13}\text{C}_{\text{ct}}$ values for samples taken along single growth layers.

It has proven much more difficult to determine values for $\delta^{18}\text{O}_{\text{w}}$. Various approaches to this problem are discussed next.

Carbon Isotopes

The $^{13}\text{C}/^{12}\text{C}$ ratio of the carbonate in calcite is always measured at the same time as $\delta^{18}\text{O}_{\text{ct}}$ during analysis of CO_2 gas on isotope ratio mass spectrometers. Data are reported as $\delta^{13}\text{C}_{\text{ct}}$ with respect to the VPDB standard. The precision of analysis is $\pm 0.1\text{‰}$. Variations in $\delta^{13}\text{C}_{\text{ct}}$ are not significantly temperature

dependent but are rather a consequence of various mixing processes during the formation of DIC.

Dating

Ages of speleothems have been obtained principally by ^{14}C and uranium (U) series dating. Electron spin resonance has been applied with limited success, possibly due to the short lifetime of trapped charges in calcite.

Radiocarbon

^{14}C is introduced into DIC and thus into speleothems through oxidation of plant-derived organic matter in the soil. Ages must be corrected for the presence of dead carbon, nonradioactive C introduced into DIC during dissolution of calcite in the soil zone. From Eq. (1), it appears that approximately half of the C atoms in HCO_3^- ions should be derived from the bedrock calcite, which in most circumstances contains no ^{14}C . Therefore, modern cave-deposited calcite should have a $^{14}\text{C}/^{12}\text{C}$ ratio approximately half that of modern carbon. The initial percentage of dead carbon (dcp) is in fact observed to range from ca. 5 to $<40\%$ (Genty et al., 2001). Lower values are presumably a result of continued exchange between soil-derived CO_2 and recharge water as it percolates through air-filled passages on the way to the cave. The initial dcp cannot be assumed to be constant at a given site but may vary as a result of changing soil activity. Errors due to uncertainty in dcp decrease with age. Speleothems dated by U series have also been used to reveal large oscillations in atmospheric ^{14}C activity (Beck et al., 2001).

U Series

^{238}U decays to a series of short-lived daughter isotopes; after a long time ($>2\text{ My}$), the activity of each of these isotopes (in disintegrations per minute in a given sample) should equal the activity of the parent ^{238}U . However, the daughter isotopes can be geochemically separated from the parent U prior to deposition of calcite because uranium is soluble in groundwater, whereas daughter Th and Pa are insoluble. The age of calcite is determined from the extent of growth of the daughter isotopes thorium-230 (^{230}Th) and ^{234}U into secular equilibrium with ^{238}U and that of protactinium-231 (^{231}Pa) into equilibrium with ^{235}U (Richards and Dorale, 2003). The activity ratio $^{230}\text{Th}/^{234}\text{U}$ increases from zero at the time of deposition to a maximum value of 1 at infinite age. The ratio of ^{234}U to ^{238}U also varies because the radiogenic ^{234}U is a 'hot atom' whose chemical properties during weathering are different from those of its parent ^{238}U .

Speleothems are well suited to U-series dating because their calcite crystals are usually large and have little tendency to recrystallize after deposition. Speleothem calcite typically contains between 100 and 1,000 parts per billion (ppb) U, whereas aragonitic speleothem contains up to 100 ppm U. Some speleothems contain detritus, which is trapped in the calcite during flooding events in caves and which contaminates the samples with ^{230}Th so that the apparent age of the freshly deposited calcite is greater than zero. Analyses of such 'dirty' calcites can be obtained by use of isochrons, in which a non-radiogenic isotope, ^{232}Th , is used to estimate the amount of

Figure 3 Analysis of layers: (a) Drawing of stalagmite showing sampling localities for Hendy test (squares) and climate records (circles); (b) Hendy test of a growth layer in a Holocene stalagmite from Marengo Cave, Indiana (R. Zhang, unpublished data). (Top graph) $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ along the left side of the growth layer are indicated by the curved line. (Bottom graph) Lack of correlation between $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$; arrow marks the top of the growth layer.

detritus (Bischoff and Fitzpatrick, 1991). Individual analyses can be corrected by using the $^{230}\text{Th}/^{232}\text{Th}$ ratio to estimate the amount of 'detrital' ^{230}Th present in the sample.

U-series isotopes are analyzed using thermal ionization mass spectrometry (TIMS; Edwards et al., 2003) or multicollector inductively coupled plasma mass spectrometry. The precision of analyses of speleothems is better than 1% of the age. Older analyses done by counting of α particles were of lower precision (5–10% of age). The practical age limit for U-series dating is approximately 500 000 years. U-Pb dating by TIMS can be used for older speleothems, although the method requires moderately high U concentrations and analysis of coeval samples with varying U/Pb ratios (Richards et al., 1998).

Paleoclimate Inferred from Oxygen Isotope Records in Speleothems

Eq. (1) shows that for speleothems formed at oxygen isotopic equilibrium, we can infer the temperature of deposition

from $\delta^{18}\text{O}_{\text{Oct}}$ and $\delta^{18}\text{O}_{\text{ppt}}$. In general, we can express a change $\delta^{18}\text{O}_{\text{Oct}}$ as

$$\Delta\delta^{18}\text{O}_{\text{Oct}} = [(d\varepsilon_{\text{ct-w}}/dT) + (d\delta^{18}\text{O}_{\text{ppt}}/dT)]\Delta T + \Delta\delta^{18}\text{O}_{\text{sw}} + \Delta\delta^{18}\text{O}_{\text{s}}$$

where sw is seawater: All meteoric water is derived from the ocean; thus, changes in $\delta^{18}\text{O}$ of seawater during the Pleistocene as a result of changes in ice volume would be reflected in $\delta^{18}\text{O}_{\text{ppt}}$. The last term is a correction to represent changes in the source of water as a result of secular shift in the average path of storm tracks. $\varepsilon_{\text{ct-w}} = (\alpha_{\text{ct-w}} - 1) \times 1000$, and $d\varepsilon_{\text{ct-w}}/dT$ is the temperature (T) dependence of the calcite–water fractionation, approximately $-0.25\text{‰}/^\circ\text{C}$. The second term, $d\delta^{18}\text{O}_{\text{ppt}}/dT$, refers to the long-term (secular) dependence of $\delta^{18}\text{O}_{\text{ppt}}$ on temperature, which is not necessarily equivalent to short-term temperature dependence as observed, for example, in annual records at a single site. The latter T dependence is typically equal to approximately $0.7\text{‰}/^\circ\text{C}$ (Rozanski et al., 1993). If the secular T dependence were also $\sim 0.7\text{‰}/^\circ\text{C}$, then the

net T -dependent change in $\delta^{18}\text{O}_{\text{ct}}$ would be approximately $0.4\text{‰}/^{\circ}\text{C}$. In tropical and subtropical regions, $\delta^{18}\text{O}$ of drip waters can also change as a result of the so-called 'amount effect,' in which $\delta^{18}\text{O}_{\text{ppt}}$ decreases with increasing volume of individual rain events (Rozanski et al., 1993). From the previous relationship, we would expect to find a positive correlation between temperature of deposition and $\delta^{18}\text{O}_{\text{ct}}$. We can test the nature of this correlation in a number of ways:

- Comparison of $\delta^{18}\text{O}_{\text{ct}}$ of modern (or interglacial) speleothems with glacial age samples
- Comparison of $\delta^{18}\text{O}_{\text{ct}}$ record with other coeval, dated paleoclimate records, such as $\delta^{18}\text{O}$ of Foraminifera from deep-sea cores or ice cores or temperatures obtained from Mg/Ca or alkenone ratios in Foraminifera
- Association between a deposit and sedimentary or paleontological deposits of known climatic signature

In published studies of $\delta^{18}\text{O}_{\text{ct}}$ vs age, the correlation between inferred paleotemperature (i.e., paleoclimate, ranging between glacial (cold) and interglacial (warm)) is either positive or negative. We can express this fact in terms of the sign of $\gamma = d(\delta^{18}\text{O}_{\text{ct}})/dT$, which can be positive or negative. This represents the tendency of $\delta^{18}\text{O}_{\text{ct}}$ to rise or fall as local climate becomes warmer or cooler. In principle, we can also have sites with $\gamma = 0$, where the positive and negative climatic effects on $\delta^{18}\text{O}_{\text{ct}}$ exactly cancel out.

Determination of $\delta^{18}\text{O}$ of Paleowaters

In order to determine paleotemperatures from speleothems deposited at isotopic equilibrium, it is necessary to determine $\delta^{18}\text{O}_{\text{w}}$ of the drip water from which the speleothem formed (see Eq. 3). $\delta^{18}\text{O}$ of drip water is close to the annual average of $\delta^{18}\text{O}_{\text{ppt}}$, the $\delta^{18}\text{O}$ value of precipitation falling on land surface above the cave (Yonge et al., 1985; Spötl et al., 2005), but may be locally affected by factors such as surface evaporation and transpiration or selective recharge of seasonal precipitation (e.g., snow meltwater). Most papers reporting $\delta^{18}\text{O}_{\text{ct}}$ data do not explicitly attempt to evaluate variation in $\delta^{18}\text{O}_{\text{ppt}}$ but merely show comparisons between excursions in $\delta^{18}\text{O}_{\text{ct}}$ and other paleoclimate proxies as noted previously. However, at least three distinct approaches have been used to estimate isotopic composition of paleowaters:

- Assuming that secular variation in $\delta^{18}\text{O}_{\text{ppt}}$ is the same as annual (seasonal) variation (Dorale et al., 1992). This assumes a particular value for $d(\delta^{18}\text{O}_{\text{ppt}})/dT$.
- Analysis of fluid inclusions in speleothem, which are presumed to represent the drip water present during growth (Schwarcz et al., 1976). This water can be extracted by crushing the sample in vacuum, and $\delta^{18}\text{O}$ and δD can be determined (Dennis et al., 2001). Although oxygen isotopes may have been exchanged postdepositionally with the calcite, the δD value of the water should be unchanged and can be used to reconstruct $\delta^{18}\text{O}_{\text{ppt}}$ from the meteoric water relationship $\delta\text{D}_{\text{ppt}} = 8 \delta^{18}\text{O}_{\text{ppt}} + \delta_0$, where δ_0 is the so-called deuterium excess. For most continental regions of the world, $\delta_0 = 10\text{‰}$, but this value may have changed through the Pleistocene. For a detailed discussion of the use of fluid inclusions, see McDermott et al. (2006).

- Specific models for variation in $\delta^{18}\text{O}_{\text{ppt}}$, such as derivation of water vapor from seawater whose $\delta^{18}\text{O}$ varied in a known fashion (Frumkin et al., 1999).

Application to Paleoclimate Studies

$\delta^{18}\text{O}_{\text{ct}}$

More than 100 papers report secular variation in $\delta^{18}\text{O}_{\text{ct}}$ of U-series dated speleothems deposited during the past 200 000 years. Most use $\delta^{18}\text{O}_{\text{ct}}$ as a proxy for paleoclimate, an approach that is analogous to the use of $\delta^{18}\text{O}$ analyses of Foraminifera from deep-sea sediments or $\delta^{18}\text{O}$ (and δD) measurements of ice cores. Most studies identify features (excursions or trends) in the speleothem records that match coeval isotopic excursions in the better known proxy records as well as records of pollen, fauna, trace elements in sediments, etc. Thus, we can describe the use of most speleothem $\delta^{18}\text{O}_{\text{ct}}$ data as providing a formal (but not quantitative) proxy for Quaternary paleoclimate. Correlations with $\delta^{18}\text{O}_{\text{ct}}$ records from U-series dated speleothems can be used to give precise dates for critical climatic transitions in other proxy records; they also have been interpreted as indicating how local climate was coupled to global climate change.

An example of a formal proxy is the study of subaqueous calcite precipitated from thermal water in a fissure at Devil's Hole, Nevada (Winograd et al., 1992). In all significant respects, this is identical to studies of speleothems, specifically in that it presents a detailed U-series dated sequence of analyses of $\delta^{18}\text{O}_{\text{ct}}$ for a laminated deposit formed at relatively low temperatures. The $\delta^{18}\text{O}_{\text{ct}}$ record (Figure 4) shows signals corresponding to all the major climatic cycles observed in deep-sea cores from 500 to 70 ka. The timing of the $\delta^{18}\text{O}_{\text{ct}}$ cycles at Devil's Hole is distinctly discordant to that inferred from the Milankovitch theory (e.g., Termination II is approximately 15 000 years earlier than expected).

$\delta^{18}\text{O}_{\text{ct}}$ records from speleothems found in the Soreq Cave and other caves in Israel (Bar-Matthews and Ayalon, 2003; Frumkin et al., 2000) show striking formal agreement between the $\delta^{18}\text{O}_{\text{ct}}$ record and data from ice cores and deep-sea sediments (Figure 5). The correspondence persists over eight oxygen isotope stages, back to 250 000 BP. $\gamma < 0$ for these sites. McGarry et al. (2004) measured δD in fluid inclusions at Soreq. Noting that $\delta_0 = 20\text{‰}$ for Israel today, they used comparisons between alkenone-based sea-surface temperatures and $\delta^{18}\text{O}_{\text{ct}}$ values to infer secular change in δ_0 .

The latter two studies made use of records that spanned glacial–interglacial transitions marked by large shifts in $\delta^{18}\text{O}_{\text{ct}}$. Studies at other sites where the dated speleothem record did not cross a termination generally display smaller scale variations in $\delta^{18}\text{O}_{\text{ct}}$, which nevertheless have been correlated with shorter term cycles in the global paleoclimate record, such as Heinrich events and Dansgaard–Oeschger (D–O) cycles. Examples follow:

Hulu Cave, China: Several speleothems give concordant, partially overlapping records that span a 70 000-year period from ca. 80 to 10 ka (Figure 6). Cycles with amplitudes of $0.5\text{–}1\text{‰}$ ($\gamma < 0$) are correlated by these authors with coeval Heinrich events (cooler periods lasting a few kiloyears

Reproduced with permission.

or less). The authors infer that these cycles record variations in monsoon activity (Wang et al., 2001).

Oman: Speleothems from caves in Oman record climatic cycles on a time scale ranging from hundreds of years to 330 ka (Fleitmann et al., 2004). $\delta^{18}\text{O}_{\text{ct}}$ in series of relatively short-lived stalagmites ranges over 8‰ ($\gamma > 0$?). These represent pluvial periods during which the source of moisture has shifted between a continental and monsoonal pattern, as shown by changing δD of fluid inclusions.

Austrian Alps: At the Klee gruben Cave, oscillations in $\delta^{18}\text{O}_{\text{ct}}$ appear to match D-O cycles seen in Greenland ice cores (Spötl and Mangini, 2002; Figure 7) and were used to provide an improved chronology for these cycles; from the correlation with D-O cycles, we infer that $\gamma > 0$ at this site.

North America: At Crevice Cave, Iowa (Dorale et al., 1998), the form of the $\delta^{18}\text{O}_{\text{ct}}$ record is correlated to that of the deep-sea record from 75 to 25 ka BP (with $\gamma > 0$). At Reed's Cave, South Dakota (Serefidin et al., 2003), oscillations in $\delta^{18}\text{O}_{\text{ct}}$ are matched to cycles in Greenland ice cores. Two speleothems from this site have opposite polarities of γ , which the authors attribute to differences in the seasonality of the supply of recharge water. Significant differences in $\delta^{18}\text{O}$ of coeval calcite deposits have been observed in speleothems from other caves.

Holocene records: Records of $\delta^{18}\text{O}_{\text{ct}}$ from Holocene speleothems have shed light on short-term, recent changes in climate in many regions. For example, Burns et al. (1998), who studied the Hoti Cave in Oman, identified pluvial periods in the early Holocene as well as the last interglacial. In Coldwater Cave, Iowa, early Holocene speleothems gave significant differences in $\delta^{18}\text{O}_{\text{ct}}$ between coeval deposits, attributable to evaporative effects on the recharge waters (Denniston et al., 1999); secular changes in $\delta^{18}\text{O}_{\text{ppt}}$ are

attributed to shifts in storm tracks over the site. Niggeman et al. (2003) showed a high-resolution $\delta^{18}\text{O}_{\text{ct}}$ record from a cave in south Germany, in which power spectrum analyses revealed the influence of solar cycles on $\delta^{18}\text{O}_{\text{ppt}}$.

The vast literature affords many other records of interest. For example, Bard et al. (2002) accounted for a drop in $\delta^{18}\text{O}_{\text{ct}}$ in an Italian speleothem approximately 170 ka BP as a result of the amount effect. This effect increased during a wet period identified by the occurrence of a sapropel layer in coeval sediments of the Mediterranean Sea (Figure 8).

Paleotemperature Records

Relatively few studies have attempted to interpret variations in $\delta^{18}\text{O}_{\text{ct}}$ as paleotemperatures, even where Hendy tests gave positive results. Dorale et al. (1992) and van Beynen et al. (2004) assumed that the secular T dependence of $\delta^{18}\text{O}_{\text{ppt}}$ was equal or similar to the seasonal value and used that relationship to derive temperatures for speleothems in Iowa and New York state (Figure 9). Although Dennis et al. (2001) analyzed fluid inclusions in speleothems, they did not use the data to calculate temperatures; Sereffiddin et al. (2005) did this for three stalagmites and showed that coeval stalagmites with differing $\delta^{18}\text{O}_{\text{ct}}$ also differed in δD of inclusions so that the calculated temperatures of deposition were the same. Mangini et al. (2005) calibrated the relationship between $\delta^{18}\text{O}_{\text{ct}}$ and T by correlating historically reconstructed average annual

temperature with $\delta^{18}\text{O}_{\text{ct}}$ values for speleothem SPA from an Alpine cave.

Carbon Isotopes

Values of $\delta^{13}\text{C}_{\text{ct}}$ directly reflect the isotopic composition of the drip water from which the speleothem grew because the temperature dependence of the carbon isotopic fractionation between calcite and DIC is relatively small. The $\delta^{13}\text{C}$ value of DIC depends critically on the sources of carbon: atmospheric CO_2 ($\delta^{13}\text{C} \sim -7\text{‰}$), carbonate derived from the bedrock ($\delta^{13}\text{C} \sim -5$ to 5‰), and oxidation of soil organic matter ($\delta^{13}\text{C} \sim -26$ to -9‰). Large variations in $\delta^{13}\text{C}_{\text{ct}}$ are observed on various timescales ranging from years (Frappier et al., 2002) to tens of kiloyears. Variations in $\delta^{13}\text{C}_{\text{ct}}$ (the $\delta^{13}\text{C}$ value of the CaCO_3) can be caused by two distinct effects, both of which are potentially influenced by climate change:

- Change in proportion of C_3 to C_4 plants growing above the cave: $\delta^{13}\text{C}$ values of C_4 plants are 17‰ higher than those of C_3 plants; most C_4 plants are grasses; shifts from forest to grassland can cause an increase in $\delta^{13}\text{C}_{\text{ct}}$ (Dorale et al., 1998).
- Change in the density of vegetation above the cave: Dissolution of limestone in the absence of soil cover occurs by reaction with atmospheric CO_2 ($\delta^{13}\text{C} \sim -7\text{‰}$), leading to higher $\delta^{13}\text{C}$ values of DIC in recharge water compared to that produced under C_3 - and even C_4 -based soils (Frumkin et al., 2000).

Figure 7 Comparison of oxygen isotope records of the Greenland ice cores and stalagmite SPA 49 from Kleegruben Cave, Austrian Alps: (a) GISP2 record; (b) GRIP, 1995 time scale; (c) GRIP, 2001 chronology; and (d) stalagmite SPA 49. Numbers refer to Greenland Interstadials. Upward arrows indicate positions of U-series samples. Dashed lines indicate major marker events used for cross-correlation. From Spötl C, and Mangini A (2002) Stalagmite from the Austrian Alps reveals Dansgaard–Oeschger events during isotope stage 3; Implications for the absolute chronology of Greenland ice cores. *Earth and Planetary Science Letters* 203: 507–518. Reproduced with permission.

In addition, the extent of exchange of the recharge water with bedrock (limestone) may affect $\delta^{13}\text{C}$ of DIC of the emerging drip waters, depending on whether or not continued air exchange is possible in the passages (fissures and joints) through which the water flows (Hendy, 1971). Finally, during progressive outgassing of CO_2 into the cave atmosphere, both equilibrium and kinetic effects can affect the $\delta^{13}\text{C}$ of the precipitated calcite (Mickler et al., 2004). These effects might be detectable as gradients in $\delta^{13}\text{C}_{\text{ct}}$ on growth layers.

Some studies have reported correlated shifts in $\delta^{18}\text{O}_{\text{ct}}$ and $\delta^{13}\text{C}_{\text{ct}}$ reflecting coupled changes in vegetation (e.g., C_3/C_4 ratios) and temperature (as reflected in $\delta^{18}\text{O}_{\text{ct}}$), whereas other studies show distinctly independent trends for each isotopic signal. Frumkin et al. (2000) showed that the trajectory of $\delta^{18}\text{O}_{\text{ct}}$ and $\delta^{13}\text{C}_{\text{ct}}$ defines simultaneous coupled changes in rainfall and temperature (Figure 10).

Future Directions and Problems

Instrumental advances in the analysis of speleothems may allow further paleoclimatic insights. Higher resolution

sampling of $\delta^{18}\text{O}_{\text{ct}}$ (and $\delta^{13}\text{C}_{\text{ct}}$) may be obtained using lasers or micromilling methods. Analyses of fluid inclusions for $\delta^{18}\text{O}$ and δD may provide better paleotemperatures, but these kinds of studies are challenged by problems in extraction and analysis of sub-microliter volumes of water. There may also be isotopic heterogeneity within the population of inclusions (Schwarcz and Yonge, 1983), partly revealed by infrared analysis (Fourier transform infrared spectroscopy) of calcite (unpublished data).

Future studies must take account of two concerns—one ethical and the other practical. Speleothems are admired for their natural beauty and should be disturbed as little as possible. Researchers must collect samples in a way that does not alter the appearance of the cave, either by using already broken stalagmites or working in caves that are in risk of destruction by erosion or human exploitation of the landscape. Second, we must be aware that, with the exception of actively growing speleothems, it is currently impossible to estimate the age of a speleothem *a priori*. Therefore, in general we cannot target a specific pre-Holocene period for study. As speleothem studies progress, previously analyzed, dated speleothems should be carefully archived for possible future research.

Terrestrial Teeth and Bones

H Bocherens and D G Drucker, Universität Tübingen, Tübingen, Germany

Introduction

Since the 1970s, stable isotopes in terrestrial teeth and bones have been providing paleoenvironmental and paleobiological information on the Quaternary period. Indeed, the skeletal tissues of an animal through its diet and drinking water yield paleoenvironmental information in the form of isotopic ratios. This information is preserved in molecules and minerals found in fossil teeth and bones.

The most commonly used pairs of isotopes are $^{13}\text{C}/^{12}\text{C}$, $^{15}\text{N}/^{14}\text{N}$, and $^{18}\text{O}/^{16}\text{O}$. Isotopes correspond to different types of atoms for a given chemical element, meaning that two isotopes of the same element have the same number of protons, but differ in the number of neutrons. For instance, an atom of ^{12}C (carbon-12) has six protons and six neutrons in its core, while an atom of ^{13}C (carbon-13) has six protons and seven neutrons. Therefore, ^{13}C exhibits a higher atomic weight than ^{12}C and is thus referred to as the heavy isotope (contrary to ^{12}C , which is referred to as the light isotope). Nevertheless, both isotopes enter in the same molecules with the same types of chemical bonds. The relative proportion of ^{13}C and ^{12}C in a given molecule is not random but depends on the relative content of both isotopes in the source of carbon used to synthesize this molecule and on the differences of behavior between both isotopes during chemical reactions.

The relative abundances of the different isotopes are much higher for light isotopes than for heavy isotopes (e.g., Koch, 2007). The variations of isotopic abundances in natural samples are very small. They are measured using an isotopic ratio mass spectrometer, which separates and quantifies the number of heavy and light isotopes of a given element. In order to ensure accuracy, measurements are performed simultaneously on the test sample and on a standard, which allows corrections that make all results comparable to one another. Due to this measurement strategy, the results are expressed as relative abundances, known as 'delta' (δ) values, which are defined as follows:

$$\delta^{\text{E}}\text{X} = \frac{^{\text{E}}\text{R}_{\text{sample}} - ^{\text{E}}\text{R}_{\text{sample}}}{^{\text{E}}\text{R}_{\text{sample}}} \times 1000\%$$

where $^{\text{E}}\text{X}$ stands for ^{13}C , ^{15}N , or ^{18}O , respectively. International reference standards have been established for $\delta^{13}\text{C}$ values (marine carbon Pee Dee Belemnite (PDB)), for $\delta^{15}\text{N}$ values (atmospheric dinitrogen), and for $\delta^{18}\text{O}$ values (an average mixture of oceanic waters called Standard Mean Ocean Water (SMOW)).

Paleobiological Tracking by Isotopes in Teeth and Bones

Bones and teeth are composed of both organic and mineral fractions which are synthesized during the lifetime of a vertebrate (Figure 1). The organic fraction of bone and dentine is

mainly formed of a protein, collagen, which contains carbon (around 40%) and nitrogen (around 15%), while the mineral fraction contains carbon and oxygen. Enamel is formed of a very small organic fraction devoid of collagen. In bone, dentine, and enamel, the mineral fraction is composed of a calcium phosphate (apatite) with many impurities, including 3–5% carbonate. The crystal size of apatite is much larger in enamel than in bone and dentine. The isotopic signatures of nitrogen are measured in the organic fraction, while oxygen isotopic signatures are measured in the mineral fraction, both in phosphate and carbonate. The isotopic signatures of carbon can be measured in the organic and the mineral phases of bone and dentine, and in the mineral fraction of enamel.

Carbon

All the carbon of an organism comes from its dietary intake, in the form of proteins, carbohydrates, and lipids. Some of these nutrients are incorporated directly by the organism and sequestered in different tissues, while other molecules are synthesized by the organism from dietary nutrients. Due to these different biochemical characteristics and isotopic fractionations, the average carbon isotopic abundance of a vertebrate is close to that of its average diet, but those recorded in a given tissue or molecule exhibit specific differences (Figure 2). The $\delta^{13}\text{C}$ values of collagen are typically 5‰ more positive than those of the average diet, while the $\delta^{13}\text{C}$ values of the carbonate fraction of bone and tooth mineral fraction is 9–14‰ more positive than that of the average diet (Cerling and Harris, 1999; Passey et al., 2005). Therefore, the $\delta^{13}\text{C}$ values of collagen and carbonate apatite are typically used to track the type of plant food consumed by herbivores and the type of plants at the base of the food web to which predators belong.

The $\delta^{13}\text{C}$ values discriminate between different types of plants, principally between marine and terrestrial plants. Among terrestrial plants, the carbon isotope signature varies between plants using the two main photosynthetic pathways, called C_3 and C_4 (' C_3 plants' and ' C_4 plants'). C_4 plants are absent or very limited in environments with a mild or cold growing season, as in Europe, Northern latitudes, and high altitudes (Ehleringer et al., 1997). When present, C_4 plants are grasses and forbs. In environments where all plants use the C_3 photosynthetic pathway, an isotopic distinction can be seen between plants growing under a closed canopy and those at the top of the canopy or growing in an open environment. The possible causes of the so-called canopy effect are the concentration of recycled CO_2 due to poor ventilation, the light attenuation, and the relative high water availability in closed canopy forest (e.g., Broadmeadow et al., 1992; Gebauer and Schultze, 1991; van der Merwe and Medina, 1991). As herbivore teeth and bones record the $\delta^{13}\text{C}$ values of their plant food, it is possible to identify which kind of plant was consumed by an herbivore, and therefore the type of environment in which it lived (Figure 3).

Figure 1 Summary of the composition of bones and teeth, with emphasis on the isotopic signatures that can be retrieved from bone, dentine, and enamel.

	Inorganic precursors	Producers (Plants)	Consumers (body average)	Consumers (bone/tooth)
Carbon ($\delta^{13}\text{C}$)	CO_2 (~ -8‰) HCO_3^- (~ 0‰)	C_3 Plants (~ -28‰) C_4 Plants (~ -13‰) Marine Plants (~ -20‰)	+ 0–1‰	+5‰ in collagen +9 to +14‰ in carbonate apatite
Nitrogen ($\delta^{15}\text{N}$)	NO_2 NO_3 NH_4 (variable) N_2 (~ 0‰)	Non N_2 fixing Plants (~ -5 to +5‰) N_2 fixing Plants (~ 0‰)	+3 to +5‰	Collagen
Oxygen ($\delta^{18}\text{O}$)	H_2O (variable according to environment) O_2	(variable according to taxon) H_2O in leaves O in nutrients O_2	H_2O CO_2	+18‰ in PO_4 +26‰ in CO_3

Figure 2 Summary of the isotopic fractionation factors associated with the transfer of carbon, nitrogen, and oxygen within food webs and the hydrological cycle, with emphasis on bone and tooth tissues. Bold arrows indicate steps where significant isotopic fractionation occurs.

Nitrogen

Nitrogen is incorporated through dietary intake in the organic molecules of an organism's tissues. It is usually measured in the collagen preserved in fossil bones. Contrarily to carbon, the isotopic signature of nitrogen is significantly enriched in vertebrate tissues relative to its average diet, typically by 3–5‰ (Figure 2; review in Robbins et al., 2005). Therefore, the nitrogen isotopic signature of a given individual depends on the isotopic signature at the base of the food web to which it belongs (in the plants), and on the position of the specimen within the food web (herbivore or predator). Not all herbivores present the same $\delta^{15}\text{N}$ values in a given ecosystem because different plants may use nitrogen under different forms, leading to varying isotopic fractionation and $\delta^{15}\text{N}$ values. For

instance, grass and graminoids typically exhibit more positive $\delta^{15}\text{N}$ values than shrubs and trees, as the latter obtain their nitrogen through symbiotic fungal mycorrhizae (e.g., Michelsen et al., 1998; Schulze et al., 1994). Global climatic factors such as aridity and temperature lead to increased $\delta^{15}\text{N}$ values of plants (Amundson et al., 2003), while $\delta^{15}\text{N}$ of plants tends to decrease with increasing altitude (e.g., Männel et al., 2007). Fire also tends to increase $\delta^{15}\text{N}$ values of plants growing after such an event (Högberg, 1997).

Oxygen

Oxygen isotopic signatures are measured in the mineral phase of enamel, dentine, or bone, in the phosphate or the carbonate

Figure 3 An example of the reconstruction of the carbon isotopic composition of the diet consumed by modern equids (horses and allies) based on their habitat. The $\delta^{13}\text{C}$ of diet has been calculated by adding 14‰ to the $\delta^{13}\text{C}$ values measured in carbonate hydroxylapatite (data from Cerling and Harris, 1999). The reconstructed diet of zebras (*Equus burchelli*) living in a Kenyan savanna exhibit $\delta^{13}\text{C}$ values similar to those of C_4 grasses, while those living in a zoo and fed with C_3 plants track this different diet, and exhibit $\delta^{13}\text{C}$ values similar to those of horse (*Equus caballus*) eating C_3 plants in a Mongolian grassland.

fractions (Kohn and Cerling, 2002). For both fractions, the $\delta^{18}\text{O}$ values are related to those of environmental water, through drinking water. However, there are complications due to the incorporation of water from food, and mixture with oxygen from respiration (Figure 2). This leads to varying species-dependent relationships between $\delta^{18}\text{O}$ values in carbonate or phosphate and $\delta^{18}\text{O}$ values in environmental water taken by the organisms. However, both $\delta^{18}\text{O}$ values are linked by a clear relationship, independent of the organism.

Variation in oxygen isotope ratios studied from terrestrial environments is ascribed to environmental temperature changes, with warmer weather resulting in more positive $\delta^{18}\text{O}$ values and cooler weather resulting in more negative $\delta^{18}\text{O}$ values in meteoric waters. However, the pattern is different in warm environments, where the temperature is higher than 20 °C. In such contexts, the $\delta^{18}\text{O}$ values decrease when the amount of precipitation increases. Local parameters, such as evaporation in ponds or streams originating at high altitudes, may provide drinking water to terrestrial vertebrates with $\delta^{18}\text{O}$ values different from those of local precipitation, and thus complicate the interpretation of the oxygen isotopic composition of fossil teeth and bones.

Chronological Resolution of Skeletal Tissues

Different tissues record the isotopic signature of food or drinking water during the period of their synthesis. Typically, bone grows during the first stages of ontogeny, but in higher vertebrates such

as mammals and birds, it continues to remodel and therefore incorporates newer carbon, nitrogen, and oxygen atoms. An adult mammal thus dies with its bone isotopic signature reflecting the last years of its lifetime. In contrast to this, mammalian dental tissues such as dentine and enamel form during a limited period of an individual's lifetime, and once formed, do not remodel. In an adult mammal, teeth exhibit isotopic signatures corresponding to the early years of the individual, depending on the chronology of tooth development for a given species. Cross sections of dentine and enamel retain their isotopic signature in a chronological order reflecting time of assimilation (e.g., Drucker et al., 2010; Fraser et al., 2008). Tooth enamel may thus record seasonal variations of $\delta^{18}\text{O}$ values (Figure 4). The level of resolution in such tissues, especially tooth enamel, is still under debate as each volume of tissue forms over a significant amount of time (e.g., Kohn and Cerling, 2002).

Physiological Effects (Suckling, Hibernation, Starvation, and Water Stress)

Some events in the life of a vertebrate can complicate the record of dietary isotopic signatures. In mammals, diet changes dramatically between the nursing and adult stages, following weaning. Maternal milk exhibits isotopic signatures different from those of the average adult diet, especially with more positive $\delta^{15}\text{N}$ values and more positive $\delta^{18}\text{O}$ values (Wright and Schwarcz, 1998). Therefore, suckling mammals exhibit

Figure 4 Variations of $\delta^{18}\text{O}$ in deer enamel reflect seasonal variations, in specimens from Wyoming and Croatia (based on Fricke et al., 1998). The differences in amplitudes and absolute values of $\delta^{18}\text{O}$ values are due to different climatic regimen in both areas.

isotopic differences relative to their adult counterparts, and tissues formed during this formative period of life, such as deciduous teeth and first molars, usually exhibit isotopic shifts relative to other teeth and bone tissues formed after weaning.

In hibernating mammals, such as bears, carbon and nitrogen isotopic signatures shift in blood during the winter sleep and these shifts are recorded in tooth dentine (Bocherens, 2004). Starvation and water stress is also a phenomenon that has been suggested to induce ^{15}N shifts in vertebrate tissue (Ambrose, 1991), but recent research on captive and wild mammals suggests that the changes in ^{15}N abundances coincident with harsh environments are most likely due to isotopic changes in the plants, while the fractionation between diet and animals remains relatively constant (e.g., Hartman, 2010; Murphy and Bowman, 2006).

Diagenetic Alteration

The chemical composition of bone and tooth is modified after an individual's death, through physical, chemical, and biochemical mechanisms called diagenesis. The intensity of diagenetic alteration depends on the time elapsed since death, but also on sedimentary conditions. High temperatures and humidity as well as high levels of microbial activity will increase the intensity of diagenetic transformation, increasing the chances of alteration of the biogenic isotopic signatures.

Organic Fraction

Collagen in fossil bones and dentine can survive for tens of thousands of years under favorable conditions. Cold and dry climatic conditions are more favorable than warm and humid ones, while cave deposits are more favorable than open-air sites. Collagen preservation in fossil skeletal remains can be

assessed by the nitrogen content of bulk sample as a proxy (e.g., Bocherens et al., 2005a).

Fossil collagen can be purified through several methods. The reliability of the isotopic signatures of ancient collagen is assessed through its chemical similarity to collagen from fresh bone. Fossil organic extracts with atomic C/N ratios lower than 2.9 or higher than 3.6 are considered unreliable, as well as those containing less than 5% nitrogen (e.g., Ambrose, 1990).

Mineral Fraction

While it is almost always possible to measure carbon and oxygen signatures from fossil bones and teeth, the key question is to determine whether the measured values correspond to those recorded in the organism's tissues when it was alive. Evaluating the extent of diagenetic alteration can be done either using the pattern of isotopic variations observed in the fossil samples as compared to equivalent modern ones, or using indirect tracers of modifications, such as crystallinity indexes and uptake of trace elements (e.g., Kohn and Cerling, 2002). It is commonly assumed that the isotopic signatures of enamel are much more stable through time than those of dentine and bone, while the phosphate fraction is more stable than the carbonate fraction. However, the phosphate fraction can be also affected under special circumstances. The best approach is to assess the extent of diagenetic alteration in each studied site using as many different proxies as possible (e.g., Kohn et al., 1999).

Reconstruction of Terrestrial Paleoenvironments

Tropical Environments

Paleoenvironments where C_3 and C_4 plants coexist are particularly favorable for isotopic tracking with carbon in teeth and

bones. Indeed, C_4 plants increase in proportion as climatic conditions become drier and warmer, and C_3 plants increase in proportion as moisture increases. As the difference between $\delta^{13}\text{C}$ values of these plants relative to C_3 plants is around 12‰, the $\delta^{13}\text{C}$ value recorded in the skeletal tissues of fossil vertebrates document these changes in the proportions of consumed plants. However, other factors such as the atmospheric pressure of CO_2 also play a role in this equation (Ehleringer et al., 1997; Koch et al., 2004). The main climatic parameter in these environments is the amount of annual rainfall, and nitrogen isotopic signatures of herbivores can be used to track past variations in aridity. Some examples are given in the following section.

Development of C_4 biomes during the late Quaternary

The open environments of the southern half of the North American continent are a place of competition between C_3 and C_4 herbaceous plants. Today, there is a clear gradient of decreasing proportions of C_4 plants toward the north, with about 10% of C_4 plants at 48° N. Carbon and oxygen isotopic studies of late Pleistocene herbivore tooth enamel from southwestern United States demonstrated the role of low atmospheric CO_2 in the expansion of C_4 plants during the Last Glacial Maximum, an expansion that could not be predicted based on temperature and precipitation changes alone (e.g., Koch et al., 2004).

Studies based on late Quaternary herbivore tooth enamel showed that the proportions of C_3 and C_4 plants in the Northern Cape Province, South Africa, did not reflect the predictions of climatic models about winter and summer rainfall regimes (Lee-Thorp and Beaumont, 1995) and documented episodes of wetter and drier conditions from 16 000 years ago (Smith et al., 2002).

Aridity

In tropical environments, aridity has been recognized as a factor influencing the $\delta^{15}\text{N}$ of herbivore collagen, with more positive $\delta^{15}\text{N}$ values under more arid conditions (e.g., Ambrose, 1991; Hartman, 2010; Murphy and Bowman, 2006; Schwarcz et al., 1999). This led to the possibility of quantifying past annual rainfall based on the $\delta^{15}\text{N}$ of herbivorous taxa, for instance, macropods (kangaroos) in Australia (Gröcke et al., 1997).

Decreasing humidity has an effect on bone because of increasing evapotranspiration in leaves, leading to $\delta^{18}\text{O}$ increase in leaf water, which is recorded in bone phosphate (e.g., Ayliffe and Chivas, 1990; Luz et al., 1990). In combination with high $\delta^{13}\text{C}$ values, the high $\delta^{18}\text{O}$ values exhibited by middle Pleistocene representatives of marsupial species that became extinct in the late Pleistocene demonstrate that these fauna could survive arid episodes, which weakens the hypothesis that increasing aridity may have led to their final extinction around 50 000 years ago (Prideaux et al., 2007).

Ecological Flexibility of Large Mammals

Isotopic tracking of habitat through the plants consumed by ancient herbivores is a taxon-free approach, and therefore can be used to document possible diet and habitat change of

some species in relationship with climate change or anthropogenic pressure. For instance, some large herbivores from the Pleistocene in Florida exhibit diet and presumably habitat stability between glacial and interglacial periods, such as tapir and mastodon that remain browsers (C_3 diet), while horses remain grazers (C_4 diet). In contrast, other species such as white-tailed deer exhibit less negative $\delta^{13}\text{C}$ values during the interglacial period, but still within the C_3 diet values, while extinct camel *Hemiauchenia* and extinct peccary *Platygonus* exhibit a clear shift from C_3 to C_4 diet between glacial and interglacial periods (DeSantis et al., 2009; Figure 5). By comparing the $\delta^{13}\text{C}$ values of modern mammals in southeastern Asia with those of the same species or related taxa in a middle Pleistocene glacial site in Thailand, it was possible to establish that some species were real forest dwellers, such as Java rhinoceros and orangutan, while others that are nowadays restricted to forest environments were dwelling in C_4 savanna, such as the small bovid *Capricornis*, a likely consequence of increasing anthropogenic pressure (Pushkina et al., 2010; Figure 5). These examples illustrate how isotopic tracking can be used to document possible habitat changes, even for species with modern relatives living in a restricted environment or with a morphology seemingly adapted to a given diet and habitat.

Temperate and Boreal Environments

In terrestrial environments, where all plants use the C_3 photosynthetic pathway, plant $\delta^{13}\text{C}$ values exhibit some differences related to environmental parameters (e.g., Heaton, 1999). In particular, plants growing under a closed canopy exhibit significantly more negative $\delta^{13}\text{C}$ values relative to those growing at the top of the canopy or in open environments. This carbon isotopic fractionation is transferred to herbivores consuming such plants in dense canopy forests. It is thus possible to track the changes of habitat for large herbivores at the beginning of the Holocene in Europe (Figure 6; e.g., Drucker et al., 2003a, 2008).

Variations in $\delta^{15}\text{N}$ values in ungulate bone collagen seem to relate to changes in soil microbial activity during the climatic oscillations that occurred in Europe since 30 000 years ago (Drucker et al., 2003a,b; Hedges et al., 2004; Richards and Hedges, 2003): low temperatures led to decreased microbial activity and thus reduced nitrogen isotopic fractionation that is transferred in plants consumed by herbivores. Indeed, a decrease in $\delta^{15}\text{N}$ values is recorded during the cold peaks of the Last Glacial Maximum and of the Younger Dryas, while an increase in $\delta^{15}\text{N}$ values is documented during the warming of the Bölling–Alleröd Interstadial and that of the early Holocene (Preboreal and Boreal). The role of climate fluctuations to explain these trends in $\delta^{15}\text{N}$ values was confirmed by the $\delta^{18}\text{O}$ values of the phosphate of the same bones that tracks temperature changes, and the observed correlation between increasing $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$ values, and hence temperature, demonstrates the relationship between increasing $\delta^{15}\text{N}$ values in red deer bone collagen and warming in this context (Drucker et al., 2009). These nitrogen isotopic excursions present geographic variations according to the intensity of the temperature changes.

Figure 5 $\delta^{13}\text{C}$ values of tooth enamel illustrate stability or changes in diet between glacial and interglacial periods in Florida (top, data from DeSantis et al., 2009) and between Saalian (glacial) and modern (interglacial) periods in southeastern Asia (bottom, data from Pushkina et al., 2010).

Figure 6 Evolution of collagen $\delta^{13}\text{C}$ values in red deer (*Cervus elaphus*) bones from French Jura and French Alps (data from Drucker et al., 2003a, 2008). The late Pleistocene samples exhibit $\delta^{13}\text{C}$ values indicative of open environments, while Holocene specimens present more negative $\delta^{13}\text{C}$ values in Jura, similar to those exhibited by modern large herbivores dwelling in a closed canopy forest. In the Alps, red deer remain in open environments, probably at higher altitudes.

Seasonality

Using carbon and oxygen isotopic variations in hypsodont tooth enamel, as in horse and bison, allowed the reconstruction of seasonal changes in consumed plant food and precipitation isotopic signatures, thus leading to a better understanding of past climatic regimen and events preceding the death of ancient animals (e.g., [Gadbury et al., 2000](#); [Higgins and MacFadden, 2004, 2009](#); [Kohn and Cerling, 2002](#); [Passey and Cerling, 2002](#)).

Reconstruction of the Paleobiology of Extinct Species

Using skeletal material from which collagen can be extracted, it is possible to reconstruct some aspects of animal diet using carbon and nitrogen isotopic signatures, because different dietary items exhibit different isotopic signatures, such as C_3 or C_4 plants, animal flesh, or food resources of marine origin. With material too old or too altered to yield collagen, the carbon isotopic signatures of tooth enamel can be used to test dietary hypotheses in contexts where different food webs start with plants exhibiting different $\delta^{13}C$ values, such as tropical environments where C_4 grasses coexist with C_3 tree leaves.

Subsistence Patterns of Ancient Hominids

Environmental and dietary changes are often linked to key stages of the evolution of hominids. In some cases, the possible impact of such changes can be tested using the isotopic signature of fossil bones and teeth.

The importance of savanna for African Pliocene–Pleistocene hominids

A hotly debated issue in the study of Quaternary terrestrial paleoenvironments is the role of savanna in the evolution of hominids in Africa. Indeed, modern African apes are restricted to forested environments, and savanna environments require special skills for exploitation by primates, such as a bipedal gait and strong social bonds. The $\delta^{13}C$ values of tooth enamel of fossil mammals, including hominids, from South Africa, ranging in age from 1.8 to 1.5 million years old, indicate a significant C_4 component in the environment, as well as significant C_4 dietary inputs for hominids of the species *Paranthropus robustus*, and *Homo ergaster* ([Figure 7](#); [Lee-Thorp et al., 2000, 2003, 2010](#)). This C_4 dietary input could be linked to the consumption of C_4 plant parts, but also to the consumption of animals feeding on C_4 plants, such as invertebrates, small vertebrates, or grazer meat. Based on other evidence such as tooth microwear and abundance of C_4 plants in the surrounding environment, it seems that the most likely explanation for this C_4 diet should include a mixture of underground plant storage organs and animals resources ([Lee-Thorp et al., 2010](#)). In East Africa, high $\delta^{13}C$ measured in some *Paranthropus boisei* seems to reflect the consumption of abundant C_4 sedges ([Figure 7](#); [Lee-Thorp et al., 2010](#)). In contrast, an older hominid from the Pliocene, *Ardipithecus ramidus*, did not incorporate C_4 resources in its diet although these resources were present in the environment ([Lee-Thorp et al., 2010](#)). This supports the view that hominid evolution is linked to savanna,

at least since about 3 Ma, but also contradicts the hypothesis that different hominids used savanna resources in differing amounts.

The Diet of Neanderthals and Early Anatomically Modern Humans

During the Upper Pleistocene, Europe was populated by a distinctive hominid form, the Neanderthals. The demise of this hominid around 30 000 years ago coincides with the appearance in Europe of anatomically modern humans, seemingly using a more sophisticated culture. Several Neanderthal fossils have yielded preserved collagen that could be analyzed for carbon- and nitrogen-stable isotopic compositions, and compared to those of Upper Paleolithic anatomically modern humans (e.g., [Bocherens et al., 1999, 2005b, in press](#); [Richards et al., 2000, 2001, 2008](#)). Comparing Neanderthals with predators such as hyenas suggests that Neanderthals consumed mainly large herbivore meat, including a large proportion of megaherbivores such as mammoth and woolly rhinoceros ([Bocherens et al., 2005b](#)). It appears also that Neanderthals living under different environmental conditions and at different periods had similar diets. Although the absolute isotopic nitrogen values of early modern humans are higher than those of the last Neanderthals ([Richards and Trinkaus, 2009](#)), possible variations in the $\delta^{15}N$ values of the whole terrestrial food webs at the same time suggest that, finally, the last Neanderthals had diets that did not differ significantly from those of early anatomically modern humans ([Drucker and Bocherens, 2004](#)). This supports the hypothesis of dietary competition between Neanderthals and anatomically modern humans ([Bocherens and Drucker, 2006](#)).

Paleodiet of Ancient Bears

Bears, as omnivorous carnivores, form an interesting group to study using the isotopic approach as their diet can be quite variable, and sometimes difficult to determine based on their morphological features. They are all the more interesting because they have an abundant fossil record, for instance, for cave bears, and cover a dietary spectrum similar to that of humans. Detecting changes in bear diet may yield direct information on the availability of food resources relevant for human diet. Moreover, the paleogenetics of ancient bears is intensively studied and combining genetic and paleodietary data through the evolution of bear lineages provides direct evidence about their evolutionary biology. Using carbon- and nitrogen-stable isotopic signatures, cave bears (*Ursus spelaeus*) were shown to be essentially vegetarian animals ([Bocherens et al., 1994, 2006, 2011a,b](#)), while the extinct giant short-faced bear (*Artodus simus*) from North America has been demonstrated to be a meat eater ([Figure 8](#); [Barnes et al., 2002](#)). Interestingly, the diet of ancient brown bears living at the same time as extinct bears from specialized species shifts when the dietary competition stops with the extinction of their competitor. For instance, brown bears from North America were vegetarian when they coexisted with the carnivorous short-faced bears, but they became much more carnivorous after the extinction of these meat-eating bears ([Barnes et al., 2002](#)).

Figure 7 Reconstruction of the paleoenvironment and paleodiet of fossil hominids from South Africa (Swartkrans Members 1 and 2, ~1.5 to 1.8 Ma) and East Africa (Olduvai East and Pening, ~1.5 to 1.8 Ma). The $\delta^{13}\text{C}$ values of *Paranthropus robustus*, and *Homo ergaster* in South Africa show that a significant amount of food resources coming from C_4 environments (most likely savanna) were consumed by these three hominid species (data from Lee-Thorp et al., 2003). In contrast to *Paranthropus robustus* in South Africa, *Paranthropus boisei* from East Africa exhibits a diet almost completely composed of C_4 food resources, while *Homo habilis* had a diet with $\delta^{13}\text{C}$ values similar to *Homo ergaster* in South Africa.

Paleodiet of Ancient Ungulates

Large herbivorous mammals often exhibit specialized diets, in connection with their tooth morphology and digestive physiology. The occurrence of some herbivorous mammals in Quaternary fossil and archaeological localities can be used to infer the paleoenvironments around the site. Isotopic analyses of fossil herbivores have sometimes yielded additional information about the ancient environments in which they used to dwell, and thus allow more precise reconstructions of the actual diet of extinct species. For instance, isotopic investigations of tooth enamel have shown that in southern North America, horses were mixed feeders consuming C_4 grasses and C_3 shrubs, while bison were grazers, eating only C_4 grasses (Koch et al., 2004). Horses have hypsodont (high-crowned) teeth and are traditionally thought to be specialized grazers. Another example of hypsodont ungulates with diverse diets are extinct camelids from North America (Feranec, 2003). Therefore, the specialized morphology of some herbivore teeth is not always indicative of specialized diet, but rather indicates dietary flexibility.

Implications for Late Pleistocene Extinctions

The possibility to reconstruct dietary and/or habitat changes through time for a given species opens the possibility to document possible ecological disruption linked to extinctions,

Figure 8 $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values of short-faced bears (*Arctodus simus*) collagen from Alaska and Yukon, compared to those of coeval herbivorous and carnivorous species (data from Fox-Dobbs et al., 2008). These isotopic data of short-faced bears plot together with carnivorous species, such as lion, scimitar-toothed cat, and wolf, clearly indicating these that short-faced bears were carnivorous.

especially in the case of the late Pleistocene megafaunal extinctions. Two main explanations are usually given for these extinctions: climate change and human impact (e.g., Koch and Barnosky, 2006). Using the isotopic signatures of extinct species until the moment they become extinct and those of surviving species before, during, and after the extinction event may provide information about the factors that could have changed at this time and therefore help to test different hypotheses. In the case of Australia, the stable isotopic tracking of megafauna paleoecology has yielded very interesting results. For instance, aridity could be ruled out as a significant factor in the extinction of megafauna as the extinct species exhibited carbon and oxygen isotopic signatures that demonstrated that they did live under arid conditions well before the time of their extinction (Prideaux et al., 2007). If humans were involved in the megafaunal extinction in Australia, the question remains whether their action was mostly direct, through overhunting, or rather indirect, through environmental disruption, in increasing wildfire frequency for instance. Isotopic tracking, together with tooth microwear analysis, did provide some answers to this question. In the case of an extinct giant short-faced kangaroo *Procoptodon*, these data suggest a diet including C_4 chenopodiaceae from dry areas and obligate drinking (Prideaux et al., 2009). Aridity would therefore not be a problem for this species, but having to go to water holes would make this species vulnerable to human predation, in contrast with other kangaroos which survived the extinction

event, and which can sustain themselves with the water contained in their plant food and do not need to drink at water holes. An additional contribution of stable isotopic tracking in the debate on megafaunal extinctions in Australia was to demonstrate that species with dietary specialization were much more affected by a collapse of ecosystem and that a critical factor for surviving was the possibility to shift diet (Miller et al., 2005). A more widespread use of this approach to megafaunal extinction on other continents should also yield valuable information. For instance, the carbon- and nitrogen-stable isotopes of the last cave lions in Western Europe dated to around 12 000 years BP suggest that they have relied mainly on reindeer as their preferred prey (Bocherens et al., 2011a). The extirpation of this predatory species in this region could then correspond to the coeval extirpation of its main prey.

Perspectives

Stable isotopes in terrestrial teeth and bones have already yielded invaluable information on Quaternary ecosystems, and this approach is expected to develop further during the coming years.

A better knowledge of isotopic variations in modern ecosystems and modern animals will most probably allow more accurate paleoenvironmental and paleodietary reconstructions to be performed based on the stable isotopic signatures of teeth and bones of Quaternary terrestrial vertebrates. Our understanding of the fractionation factors in tissues prone to fossilization still needs improvement, based on controlled diet experiments of species closely related to the fossil taxa under study, and on investigations of large mammals in monitored wild contexts. Also the chronology of isotopic records in incrementally grown tissues, such as tooth enamel, needs more accurate quantification in the species found in Quaternary fossil assemblages.

The impact of diagenetic alteration on the isotopic signatures of teeth and bones needs to be better understood, especially when dealing with the mineral fraction of fossil vertebrates.

Collagen is currently used for its carbon and nitrogen isotopic signatures, but it could yield the isotopic signatures of additional chemical elements. For instance, the amount of deuterium, the stable heavy isotope of hydrogen, could be used to study paleoclimates and possible migrations, as it varies in a way similar to oxygen in relationship with temperatures (Bowen et al., 2005; Cormie et al., 1994). The isotopic signatures of sulfur in collagen may be used to improve paleodietary reconstructions and to provide identification of geographic origin (Richards et al., 2003).

Improving biomolecular technologies will allow the analysis of isotopic signatures of other organic compounds, such as osteocalcin, single amino acids, cholesterol, and fatty acids, in fossil bones and teeth (e.g., Corr et al., 2005; Smith et al., 2005, 2009). This is expected to lead to breakthroughs in retrieving paleobiological information at different timescales within a single individual, and in obtaining isotopic paleobiological signals in fossil material older than around 100 000 years.

Introduction

The elements carbon, hydrogen, and oxygen, which are the main constituents of terrestrial organic material, each have more than one stable (nonradioactive) isotope with nearly identical chemical properties but a difference in mass. By convention, the ratio of two stable isotopes is expressed relative to a standard using the delta notation in parts per mil (‰). In terrestrial organic material, the relevant isotope ratios are $\delta^{13}\text{C}$, $\delta^{18}\text{O}$, and $\delta^2\text{H}$ (or δD for deuterium). They are measured by first producing a suitable target gas, by either combustion or pyrolysis, and subsequent analysis by isotope ratio mass spectrometry (McCarroll and Loader, 2005). Since physical and biochemical processes are often sensitive to differences in mass, the ratios of the stable isotopes in organic material are not the same as those in the source (usually air or water). The degree of difference between the source and the organic product, or the total fractionation, may contain information not only on the source material, including the carbon isotopic ratios of atmospheric CO_2 , and the isotopic ratios of source water, but also on the degree of change that occurred as a result of environmental influences on fractionation. The isotopic signatures of the sources and changes due to environmental influences both may contain paleoenvironmental information. The most important continuous archives of terrestrial organic material suitable for stable isotopic analyses are tree rings and peat profiles.

Stable Isotopes in Tree Rings

As natural archives of paleoclimate information, trees have the great advantage that, under many conditions, they produce annual rings. A few tree species can live for millennia, but even for shorter-lived species, counting, measuring, and cross-matching the rings of many overlapping generations allow very long, well-replicated, annually resolved, and precisely dated chronologies to be constructed. Variations in the width of the annual rings in these long chronologies provide one of the most commonly used high-resolution 'proxy' sources of paleoclimate information. Suitable trees are widespread, and sampling and measuring are relatively inexpensive. However, the time series of ring widths need to be analyzed very carefully because they contain trends that relate to the age of the trees, and removing these trends without degrading the climate information is challenging. It is particularly difficult to retain long-term, low-frequency climate changes. One attraction of stable isotopes in tree rings is that the time series probably does not contain long-term trends related to tree age, and may thus retain climate information at all temporal frequencies. Also, the growth of trees, and therefore the annual ring width, is influenced by a myriad of interconnected factors,

and so is difficult to model mechanistically. The interpretation of ring-width series, therefore, generally relies on statistical inference and in particular on regression techniques. In contrast, the factors that control the fractionation of isotopes in trees are quite well understood and relatively simple in comparison, so that a mechanistic understanding of the processes involved, and of the ecophysiology of particular tree species, can be used to guide paleoenvironmental interpretations. Early attempts at 'stable isotope dendroclimatology' used blocks of wood covering several years and/or pooled the wood of several trees prior to analysis. However, recent advances in sample preparation and mass spectrometry have greatly accelerated the rate at which organic samples can be analyzed, and the use of stable isotopes in tree rings to reconstruct past climate is a rapidly expanding field of research (McCarroll and Loader, 2004, 2005).

Isotopic Fractionation by Trees

The main constituents of wood are cellulose, which forms the framework of cells, and lignin, which adds strength. These components contain carbon that is taken from CO_2 that enters the leaves via the stomata, whereas the oxygen and hydrogen are derived from water taken up through the roots. As a consequence of this composite structure, in ancient samples there is a potential for preferential decomposition of lignins or cellulose. To avoid these effects, a single compound is isolated from the wholewood prior to isotopic analysis. Typically, the fraction analyzed is the cellulose, as this signal is derived exclusively from the dated rings of the tree. However, studies with lignin have also been demonstrated to preserve climatic information at high (annual) resolution (Loader et al., 2003).

The stable isotopes of carbon in CO_2 are fractionated first as the gas enters the stomata and again as it is taken up by the photosynthetic enzyme, in both cases leading to an increase in the relative abundance of the lighter isotope and therefore a reduction in $\delta^{13}\text{C}$ (more negative values). The first step occurs because lighter molecules diffuse through a gap more easily than heavier ones. As gas molecules bounce off each other, the lighter ones bounce furthest, so the fractionation due to diffusion is controlled by the difference in mass. This means that the fractionation of carbon as it diffuses into the stomatal chambers remains at about -4.4‰ , almost irrespective of the environmental conditions or the size of the stomatal opening. It only increases under the rare conditions when the stomatal opening is so small that molecules bouncing off the sides, rather than each other, become important. The second fractionation, when the CO_2 is taken up by the photosynthetic enzyme, is similarly insensitive to environmental conditions, including temperature, and remains at about -27‰ (Farquhar et al., 1982) (Figure 1).

Figure 1 Diagram of a needle-leaf tree showing the main controls on fractionation of carbon isotopes and the environmental factors that influence them. Discrimination against ^{13}C (Δ) is expressed in per mil (‰) relative to a standard (Vienna Pee Dee Belemnite (VPDB)). Discrimination occurs during diffusion through the stomata (a) and again during carboxylation (b). Where the ambient concentration of CO₂ (c_a) is known, the key variable is the internal concentration of CO₂ (c_i), which is controlled by the balance between stomatal conductance (g) and photosynthetic rate (A). This relationship can be used to calculate intrinsic water use efficiency (iWUE). After McCarroll D and Loader NJ (2004) Stable isotopes in tree rings. *Quaternary Science Reviews* 23: 771–801.

The insensitivity of the fractionations to environmental variables means that the isotopic ratios of the gas that enters the leaf is controlled by that of the ambient air, so that tree-ring $\delta^{13}\text{C}$ must be affected by changes in the isotopic composition of the atmosphere. The second fractionation, however, does not act on ambient air but on the CO₂ in air that is within the stomatal chambers. As CO₂ is removed and assimilated, the relative abundance of the heavier isotopes remaining in this intercellular CO₂ must increase, and as more of this enriched CO₂ is assimilated, the $\delta^{13}\text{C}$ of the resulting sugars must also increase, even though the fractionation remains at about -27‰.

The fractionation of carbon that occurs in tree leaves is not a direct response to environmental variables, but rather a measure of the relative rates at which CO₂ enters and is removed

from the stomatal chambers. The controls are therefore stomatal conductance and photosynthetic rate. Where stomatal conductance is high relative to photosynthetic rate, the assimilates will have low $\delta^{13}\text{C}$ values, but where stomatal openings become restricted in response to moisture stress, or when photosynthetic rates are very high, the internal concentration of CO₂ will drop, becoming enriched in ^{13}C and yielding assimilates with higher $\delta^{13}\text{C}$ values. The sugars produced in the leaf may be used directly to produce new wood, in which case, the climatic conditions that influenced the signal imparted in the leaf will be transferred to the wood cells produced in the same year, or they may be stored and remobilized later, leading to further fractionation and a lag between the climatic forcing and its expression in the isotopic composition of the tree ring (Helle and Schleser, 2004). This effect is most pronounced in

the earlywood fraction of the tree ring; consequently, to avoid remobilized carbon, and thus maintain the annual resolution of the signal, many recent studies have used only the latewood portion of tree rings, which forms during the summer.

The ratios of the stable isotopes of oxygen and hydrogen in tree rings are more complex than those of carbon because they conflate two separate signals: a source water signal and an isotopic enrichment due to leaf transpiration. The isotopic ratios in precipitation are controlled by a number of factors (Darling et al., 2005), including (but not always dominated by) temperature. However, to regard water-isotope ratios in tree rings as a simple paleothermometer is overly simplistic. The rainfall must first reach the tree roots, so the depth and structure of the root system of different species can mean that water of different ages is utilized. Wood formed in a given summer may, therefore, utilize water molecules from summer rainfall, precipitation from the previous winter (Robertson et al., 2001), or over a much longer time period. There is no fractionation when roots take up the soil water, but on reaching the leaves, evaporation results in a preferential loss of the lighter isotopes. The controls are very similar to those that govern fractionation due to evaporation from a lake, though there is an additional fractionation as water vapor diffuses through the stomata and leaf boundary layer. Although there is a small temperature effect, the dominant controls are the isotopic composition of water in the atmosphere, relative to the source water, and the difference between the ambient and intercellular vapor pressures. Low air humidity thus leads to greater enrichment of the heavier isotopes of both oxygen and hydrogen. Backward movement of isotopically enriched water from the sites of evaporation is opposed by the supply of unenriched source water, so the isotopic values of total leaf water are lower than those at the sites of evaporation (Barbour et al., 2001). There is a further fractionation when the water is incorporated in sucrose formed in the leaf, leading to a further enrichment of ^{18}O (+27‰) but a larger and less certain depletion of deuterium (−100‰ to −171‰) (Figure 2).

The situation is further complicated because a proportion of the oxygen atoms in the sugars that form in the leaf are able to exchange with (unenriched) atoms from xylem (source) water moving up the stem at the site where the wood is formed. The amount of exchange is difficult to predict, but controls the relative importance of the source water and leaf enrichment signals. The potential for exchange is probably larger for lignin than for cellulose. When sugars are used to form wood cells, there is a large fractionation of hydrogen in the opposite direction and similar in magnitude to that which occurs when the sugar is formed (+144‰ to +166‰), and as with oxygen, there is potential for exchange with xylem water and thus for altering the balance of the two signals (McCarroll and Loader, 2004, 2005).

Interpreting Stable Isotopes from Tree Rings

Early work on stable isotopes in tree rings interpreted changes in both the carbon- and the water-isotope ratios in terms of changes in temperature, treating them as paleothermometers. Unfortunately, this is a gross oversimplification and in reality none of them is controlled in a simple way by a single climatic

variable. Carbon-isotope ratios record the balance between stomatal conductance and photosynthetic rate, whereas the water isotopes take part of their signal from the isotopic ratios of the source water but then enrich it by evaporation in the leaf. Although each of these isotopes may, under certain circumstances, be strongly correlated with temperature, it is unlikely that temperature is actually the controlling factor. Temperature may correlate with carbon-isotopic ratios through covariance with changes in sunlight, which drives photosynthesis, or through covariance with relative humidity and rainfall, which control stomatal conductance. Temperature is only one of the factors that influence the isotopic ratios in source water, and although there is a small direct influence of temperature on fractionation at the sites of evaporation in the leaf, the dominant control is the difference in vapor pressure inside and outside of the leaf, which is strongly dependent on air relative humidity. Thus, although the correlation with temperature during the period when meteorological records are available can be used to reconstruct past temperatures using regression-based techniques, it is important to remember that correlation is not causation and that any change in one of the real controlling factors will change the isotopic ratios, irrespective of whether there was a change in temperature. Since the instrumental period coincides with the period of greatest anthropogenic disturbance, to both forests and the atmosphere, changes in the relationship between temperature and the controlling factors may well have occurred. Of course, this logic applies to most natural archives used as proxy sources of paleoclimate information, it is simply more apparent for tree ring stable isotopes. This is because trees provide absolute temporal control and a clearer (mechanistic) understanding of signal preservation than is often observed in other terrestrial paleorecords.

Rather than relying on the correlation between temperature and isotopic ratios to reconstruct paleotemperatures using 'black box' methods based on regression, it might be more enlightening to take advantage of the mechanistic understanding of fractionation and attempt to tease out the real environmental controls. This can be achieved in part by careful selection of trees and sites so that one control is likely to dominate (McCarroll and Loader, 2005). Shallow-rooted trees on sites with very freely draining soils, for example, are likely to be sensitive to the stomatal conductance control on carbon-isotope ratios and to respond rapidly to changes in source water-isotope ratios. Deeply rooted trees with access to a plentiful supply of groundwater, on the other hand, are likely to yield carbon-isotope ratios that are more responsive to changes in photosynthetic rate and water-isotope ratios, in which the source water signal is smoothed so that the evaporative enrichment signal is clearer. Perhaps even greater potential lies in combining different isotopes and other paleoclimate proxies that can be extracted from trees in a multiproxy approach that is guided by theory rather than purely by statistical inference (McCarroll et al., 2003).

Application of isotopic analysis is not limited to annual increments. Through high-resolution sampling of individual rings, rhythmic trends and periodicities can be identified that can be related to plant physiological processes occurring within the growth cycle (Helle and Schleser, 2003). This approach can be taken forward further to tropical species that do

Figure 2 Diagram of a broad-leaved tree showing the main controls on the fractionation of oxygen isotopes and the environmental factors that influence them. There is no fractionation when source water is taken up by the roots. The level of enrichment of leaf water above source water, at the sites of evaporation ($\delta^{18}\text{O}_e$), depends upon the proportional depression of water vapor pressure by the heavier H_2^{18}O (ε^*), fractionation as water diffuses through the stomata and leaf boundary layer (ε_k), the isotopic composition of water vapor in the atmosphere, relative to source water ($\Delta^{18}\text{O}_v$), and the ambient and intercellular vapor pressures (e_a and e_i). The same equations control the fractionation of hydrogen isotopes, though the fractionation factors are different. After McCarroll D and Loader NJ (2004) Stable isotopes in tree rings. *Quaternary Science Reviews* 23: 771–801.

not exhibit regular annual banding, yet where an apparent (possibly seasonal/annual) cyclicity may be identified in their isotopic composition.

Stable Isotopes in Peat Profiles

Peat deposits provide one of the best-known archives of paleoclimate information for the Holocene. Peat accumulation can be continuous and the acidic conditions are suitable for the preservation of a wide range of organic materials including leaves, other plant macrofossils, and pollen. The preserved

macrofossils, or identifiable remains of the peat-forming plants, can be radiocarbon-dated to provide a chronology. Stable isotopic analysis of leaves provides a potential source of information on the stable isotope ratios in the vegetation surrounding the peat at different times (Rundgren et al., 2000). More attention has been paid, however, to isotopic analysis of the mosses and other peat-forming plants.

Some mosses, such as *Sphagnum*, differ from the higher plants in that, although photosynthesis appears to follow the C3 pathway, they do not possess functioning guard cells around their stomata and hence do not regulate water loss. The dominant controls on the fractionation of carbon isotopes,

therefore, are likely to be the isotope ratios of the source gas, photosynthetic rate, and the resistance to diffusion of CO₂. Resistance to diffusion is likely related to the thickness of the water layer, so that at higher moisture contents mosses would be expected to yield less negative values. This relationship with wetness is the opposite to that seen in the higher plants, including trees, where dry conditions lead to a reduction in stomatal conductance, a decline in internal concentration of CO₂, and thus to less negative $\delta^{13}\text{C}$ values. In the mosses, resistance to diffusion is equivalent to stomatal conductance, but a reduction in moisture content decreases resistance to diffusion, leading to more negative $\delta^{13}\text{C}$ values. This is supported by results from several species of *Sphagnum* from two peat bogs in Ireland, where plants growing on relatively dry hummocks yielded higher $\delta^{13}\text{C}$ values than those in wetter hollows (Price et al., 1997).

As with other plants, the isotopic ratio of the source gas used by mosses must be reflected in the isotopic ratios of the photosynthetic products. However, whereas mature trees have access to well-mixed atmospheric gases, mosses on the surface of a peat mire may be in contact with significant amounts of recycled CO₂, which will produce relatively light $\delta^{13}\text{C}$ values. Price et al. (1997) have argued that this effect will be most marked where the mosses are submerged, and particularly where there is a low density of living plants in pools. For this reason, they argue that hummock-top species of *Sphagnum* are likely to be the most useful for stable carbon-isotopic analysis.

The differences in carbon-isotope fractionation between mosses and sedges in peat have been proposed as a relatively high-resolution method for reconstructing past changes in the concentration of atmospheric CO₂, perhaps linked to changes in thermohaline circulation (Figge and White, 1995). The efficacy of this technique is contested, however, since some of the differences could be due to the effects of changes in moisture regime on fractionation by the mosses.

The fractionation of the water isotopes in mosses should be the same as for higher plants, in that isotope ratios should reflect the isotopic values of the source water and isotopic enrichment due to evaporation. However, where the plants in question are fully submerged, evaporation does not take place and so the isotopic values in the plant tissue should mirror the isotopic values of the source water, with a consistent offset due to fractionation during photosynthesis. Oxygen isotope results from *Sphagnum* cellulose confirm that submerged species yield values that mirror those of the water, whereas emergent species give a wider range of values, reflecting differences in the amount of evaporation (Zanazzi and Mora, 2005). Stable hydrogen and oxygen-isotopic analysis of submerged moss species from peat profiles may provide a powerful proxy for past changes in the isotopic composition of the bog water.

Stable Isotope Analysis of Pollen

The physical (numerical) analysis of pollen assemblages preserved in terrestrial and marine sedimentary archives provides one of the most established and powerful tools for the study of paleoecology and vegetation dynamics throughout the Quaternary.

More recently, significant interest has developed into the (CHO) isotopic analysis of pollen grains. This approach has only been made feasible through the development of continuous-flow mass spectrometry methods, which require smaller sample sizes than traditional off-line preparation and dual inlet techniques. A series of pilot studies has emerged within the last decade, which serves to identify the potential of this approach for paleoecological research. Loader and Hemming (2004) provide a review of the current state-of-the-art and discuss the current limitations and research opportunities for this emerging proxy.

Like many terrestrial paleoarchives, pollen grains comprise a range of chemical components. Typically, a single grain may be considered to consist of three principal structural elements: an inner nucleus which contains the reproductive and genetic materials, a cellulose inner layer or 'intine,' and a β -carotenoid ester outer layer or 'exine,' which represents ca. 65–80% of the grain and together may be further bound with lipids or coated with a thin polysaccharide layer. There is still debate as to the exact chemical structure of the exine, although it is believed to approximate C₉₀H₁₅₀O₃₃. Although incredibly resistant, being of a composite origin, pollen is susceptible to differential diagenesis. Typically, it is the exine that is selected for isotopic analysis, as it is this component that preserves in its morphology, the key to the species/genus of plant from which it originated (Figure 3).

Preparation of Pollen Samples

For conventional palynology, exines are purified from the sediment matrix through a suite of aggressive chemical processes. Isotopic analysis of raw and extracted modern pollen exines exhibit a species-specific isotopic offset of between ca. 2 and 4 per mil $\delta^{13}\text{C}$. Consequently, to avoid the effects of differential diagenesis, a chemical preparatory approach should be considered when preparing pollen extracts from the paleoarchive for isotopic analysis. Direct transfer of methodologies developed for conventional pollen preparation is likely to be inappropriate, as acetylation, for example, has been shown to contaminate isotopically the end product.

Carbon-isotopic analysis of modern pollen samples from different species have been shown to record different signals. It is therefore likely that in order to achieve a robust paleo-record, selection of a single species or genus may be required. At present, the greatest limitation to the wider application of this method lies in the extraction and purification of sufficient pollen grains for isotopic analysis. Sample concentration by sieving, dense media separation, and centrifugation, followed by manual picking, provide one of the most accessible methods currently available. Less time-consuming sample-preparation methods are urgently required. Application of fluid dynamic separation (split flow lateral transport thin separation (SPLIT)) methods or automated image recognition and micromanipulation exhibit the greatest potential for future advances in this field. Nevertheless, even using existing labor-intensive picking methods, it is possible to extract sufficient material for either radiocarbon dating or stable isotope analyses.

Figure 3 (a) Untreated *Pinus sylvestris* pollen composite-stained with safranin-fast green, highlighting the cellulose intine of the grains (green). Note: No cellulose is present in the saccae and the exine is only partially stained (pink) due to the presence of a polysaccharide layer. (b) Acid treated *Pinus sylvestris* pollen composite-stained with safranin-fast green. The strong safranin staining of the exine (pink) demonstrates removal of the outer polysaccharide layer. The cellulose intine has been completely removed. After Loader NJ and Hemming DL (2000) Preparation of pollen for stable carbon isotope analyses. *Chemical Geology* 165: 339–344.

Large, easily extractable genera such as *Picea*, *Abies*, and, to a lesser extent, *Pinus* represent likely candidate species for paleo-ecological reconstruction based upon isotopic analysis (500 spruce grains $\approx 8 \mu\text{g}$ of carbon). Species differences are less important in applications where Poaceae pollen have been analyzed isotopically to establish the relative proportion of grassland community species which use either C3 or C4 photosynthetic mechanisms. Changes in the isotopic ratio of the bulk Poaceae signal reflect within it changes in (paleo)grassland composition from which paleoclimate may be inferred (Amundson et al., 1997). In all cases, representative sampling and thorough replication are essential, as is an understanding of pollen production, dispersal, and preservation. Interpretation of the isotopic data should also include consideration of the physical pollen record.

Environmental Signals

Unlike the formation of cellulose in tree rings, the imprinting of an environmental signal in pollen grains is still a subject

of some debate. It is likely that many of the mechanisms described for tree rings are relevant to those responsible for pollen formation; however, the subsequent fate of the photo-assimilates and the mechanisms and pathways they follow during their remobilization/use in the production of pollen remains largely unknown. Empirical studies provide some insight into these processes. Carbon isotopes are likely to reflect the composition of the photosynthates occurring during the formation of the pollen initials (year $t - 1$) and the conditions prevailing during pollen maturation and photosynthesis prior to pollen fly (year t). Mechanistically, the oxygen- and hydrogen-isotope ratios of the photosynthates used to form the pollen should reflect the composition of the source water, with evaporative enrichment (and potentially subsequent re-exchange with source water). Initial investigations have broadly demonstrated this relationship for hydrogen, but it would appear that the signal preserved in the oxygen-isotope ratio of pollen exines is more complex and may reflect the relative degree to which the source water signal is transferred to the pollen grain or differences in biochemical fractionations occurring along the respective photosynthetic pathways. Further work is needed to evaluate and better quantify these processes.

Introduction

The carbon- (expressed in ‰ as $\delta^{13}\text{C}$ (VPDB)) and oxygen- ($\delta^{18}\text{O}$ (VPDB)) isotopic composition of surficial carbonate has been widely used in paleoclimatic and paleoenvironmental reconstruction during the Quaternary. In surficial carbonates we include: soil carbonates and sphaerosiderites, spring travertines, and a variety of early meteoric cements, usually formed in the saturated zone. Other important surficial meteoric carbonates covered by other articles in this Encyclopedia include lacustrine (see [Lake Sediments](#)) and speleothem (see [Speleothems](#)) carbonates. There is a large literature on this topic that cannot be comprehensively reviewed in this short article. Instead, we examine a few representative soil carbonate records of environmental change over the Neogene and Pleistocene, and groundwater carbonate records from Devils Hole, Nevada.

Formation of soil carbonates and groundwater carbonates can be viewed as expressions of a single groundwater flow continuum, summarized in [Figure 1](#). The general equation for weathering (to the right) and calcite precipitation (to the left) in this continuum is:

Here we use calcite as the parent material but we could just as easily have used most silicate minerals in its place. Calcite or silicate dissolution begins in the soil (vadose) zone in the presence of elevated soil pCO_2 (>350 ppmV) produced by plant respiration and decay. This dissolution process can continue below the vadose zone and into the saturated zone until significant levels of supersaturation with respect to calcite are reached, whereupon carbonate precipitates. In dry soil settings, supersaturation often develops prior to the next soil flushing event, due largely to soil dewatering by plants and by evaporation. In the shallow saturated zone, such in some caves and springs, calcite precipitation is driven by off-gassing of dissolved CO_2 . In deeper systems, such as Devils Hole in southern Nevada, decompression during ascent of deeply circulated groundwater may induce carbonate formation.

Carbonate is among the most abundant of secondary minerals in the geologic record, and can form in a large range of burial depths and conditions. The use of the soil diffusion model (see below) as an interpretive framework for carbon-isotope values in soils assumes that the material being analyzed is a well-preserved soil carbonate. One should rely on a suite of features for accurate identification of soil carbonate over other secondary forms of calcite cementation. These criteria include (1) firm associations with other soil features ([Figure 2](#)), (2) nodule form ([Figures 2\(b\)](#) and [\(c\)](#)) and micritic texture ([Figures 2\(i\)](#) and [\(j\)](#)), (3) reworking of nodules into contemporaneous channels ([Figures 2\(h\)](#) and [\(i\)](#)), and (4) the absence of detrital carbonate contamination. (see [Soil Morphology in Quaternary Studies](#)).

The Devils Hole calcites in southern Nevada lie toward the distal end of a large ($\sim 12\,000\text{ km}^2$) flow system hosted largely by fractured carbonate rocks. Coarse-grained, laminated calcites coat fractures below the top of the water table ([Figure 3](#)). Access to these fracture coatings is possible at Devils Hole, where collapse of the roof of one large fracture has exposed the aquifer and permitted divers to enter, as well as at various locations in nearby Death Valley, where recent tectonism has exhumed other fracture coatings ([Figure 3](#)).

The Oxygen-Isotopic Composition of Surficial Meteoric Carbonates

Background

The oxygen-isotopic composition of surficial meteoric carbonate ($\delta^{18}\text{O}_{\text{cc}}$) (VPDB) is determined by both air and local vadose zone temperature, by the $\delta^{18}\text{O}$ value of rainfall ($\delta^{18}\text{O}_{\text{p}}$), and by soil evaporation.

Temperature effects

Temperature can potentially influence $\delta^{18}\text{O}_{\text{cc}}$ values in two ways, through the influence of (1) soil temperature on fractionation between water and calcite during soil carbonate formation, and (2) air temperature on $\delta^{18}\text{O}_{\text{p}}$.

The temperature dependence of the fractionation factor ($\alpha_{\text{c-w}}$) between calcite and water is:

$$\alpha_{\text{c-w}} = \exp\left(\frac{(18,030/T) - 32.42}{1000}\right) \quad [2]$$

with temperature (T) in K ([Kim and O'Neil, 1997](#)). This equates to an approx. -0.22 to -0.24‰ C^{-1} change in $\delta^{18}\text{O}_{\text{cc}}$ values with soil temperature at constant $\delta^{18}\text{O}_{\text{p}}$. Temperature in the shallow vadose zone (2–10 m) approximates mean annual temperature (MAT), reducing potentially large seasonal temperature extremes. At depths of >100 m, the effects of local geothermal gradients ($2\text{--}3\text{ °C per }100\text{ m}$) will develop, as in the case of the mildly geothermal waters at Devils Hole.

The oxygen-isotope value of precipitation ($\delta^{18}\text{O}_{\text{p}}$) is correlated with air temperature at mid- to high latitudes. The slope of this dependence (the 'Dansgaard relationship') ranges between $+0.2$ and 0.9‰ C^{-1} but averages $+0.6 \pm 0.1\text{‰ C}^{-1}$ in most mid-latitude settings of soil carbonate formation.

These two influences of temperature on $\delta^{18}\text{O}_{\text{cc}}$ values are opposite in sign ($-0.23 \pm 0.1\text{‰ C}^{-1}$ versus $+0.6 \pm 0.1\text{‰ C}^{-1}$). They should combine to increase $\delta^{18}\text{O}_{\text{cc}}$ values by $+0.25$ to $+0.5\text{‰ C}^{-1}$. In agreement with this prediction, in carbonates from modern soils with rainfall exceeding $\sim 10\text{ cm yr}^{-1}$ (low evaporation), the observed slope is $+0.44\text{‰ C}^{-1}$ ($r^2=0.56$) ([Figure 4](#)).

Figure 1 Summary diagram of formation processes for soil carbonates (inset), spring, and deep groundwater (Devils Hole) carbonates.

The $+0.25$ to $+0.5\text{‰}$ C^{-1} dependence means that the large uncertainties in the $\delta^{18}\text{O}_\text{p}$ value produce major uncertainties in the reconstructed paleotemperature, but conversely, that large uncertainties in paleotemperature produce relatively small uncertainties in the reconstructed $\delta^{18}\text{O}_\text{p}$. This is why the $\delta^{18}\text{O}_\text{cc}$ values are poor paleothermometers but can be useful in constraining paleo- $\delta^{18}\text{O}_\text{p}$ values.

$\delta^{18}\text{O}$ composition of precipitation ($\delta^{18}\text{O}_\text{p}$)

$\delta^{18}\text{O}_\text{p}$ is a strong predictor of $\delta^{18}\text{O}_\text{cc}$ values, especially in temperature soils where evaporation rates are minimized (Figure 5). The oxygen value of precipitation is influenced by several factors, including air temperature, changes in the $\delta^{18}\text{O}$ value of seawater ($\delta^{18}\text{O}_\text{seawater}$) and, at low latitudes, by changes in rainfall amount, referred to as the amount effect. The amount effect is the dominant control on $\delta^{18}\text{O}_\text{p}$ at low latitudes and is $\sim -1.5\text{‰}$ per 10 cm rainfall globally (Rozanski et al., 1993). This effect is not only visible in rainfall records from island stations, but also in monsoonal systems, where the $\delta^{18}\text{O}_\text{p}$ values during the summer rainy season are much lower than in the winter nonrainy season.

The ocean is the source of most atmospheric moisture, hence changes in the $\delta^{18}\text{O}_\text{seawater}$ values should translate directly into changes in $\delta^{18}\text{O}_\text{p}$ values. During glacial periods in the Quaternary, $\delta^{18}\text{O}_\text{seawater}$ values increase by $\sim 1.0\text{‰}$. At mid- to high latitudes, increases in $\delta^{18}\text{O}_\text{seawater}$ during glacial periods would dampen decreases in $\delta^{18}\text{O}_\text{cc}$ values due to lower temperatures.

Soil water evaporation

When RH is high, $\delta^{18}\text{O}_\text{soilwater} = \delta^{18}\text{O}_\text{p}$, as discussed above. In sphaerosiderites and groundwater carbonates, the evaporation term is probably unimportant. In soils from dry regions, evaporation can strongly increase $\delta^{18}\text{O}_\text{soilwater}$ values with respect to $\delta^{18}\text{O}_\text{p}$ values. In general, evaporative enrichment in ^{18}O of water increases linearly with decreased relative humidity. Results from the Atacama Desert and the Death Valley portion of the Mojave Desert (Figure 5) illustrate the strong effects of evaporation on $\delta^{18}\text{O}_\text{cc}$ values.

The Carbon-Isotopic Composition of Surficial Meteoric Carbonates

Organic processes tend to dominate the $\delta^{13}\text{C}$ value of surficial carbonates. In this article, we focus on the carbon isotopes in soil carbonates, since the $\delta^{13}\text{C}$ values of other types of carbonates, although of interest from a process point of view, do not contribute much to paleoenvironmental reconstruction. For example, spring travertines and many cave speleothems (Fantidas and Ehhalt, 1970; Hendy, 1971; reviewed in Quade (2003)) undergo kinetic enrichment in ^{13}C due to CO_2 off-gassing and evaporation, greatly reducing their usefulness in paleoclimatic reconstruction. The $\delta^{13}\text{C}$ value of sphaerosiderites (Ludvigson et al., 2002) and other meteoric calcites can be strongly influenced by methanogenesis, especially in wet-logged, organic-rich settings. In other instances, water-

Figure 4 $\delta^{18}\text{O}_{\text{cc}}$ values from modern soils vs. mean annual temperature. The slope (+0.44 ‰/°C) of the best fit line matches the slope predicted by temperature effects of +0.25 ‰/°C to +0.5 ‰/°C.

limestone interactions can alter the primary (surficial) $\delta^{13}\text{C}$ value of dissolved bicarbonate, such as in speleothems (Baker et al., 1997) and groundwater calcites (Devils Hole: Reviewed in Quade (2003)).

Soil Carbonate, Climate, and Vegetation

The $\delta^{13}\text{C}$ value of soil carbonate is largely determined by the proportion of C_3 and C_4 plants growing in the immediate vicinity. Globally, C_3 plants include virtually all trees, almost all shrubs, and those grasses growing under low-light and cool conditions. They average -27‰ in $\delta^{13}\text{C}$ (PDB). C_4 plants occur in 18 plant families; in terms of biomass they comprise mostly grasses and sedges. Of all the grass species, 21% are C_4 , and compared to C_3 grasses, C_4 grasses tend to favor high-light and higher temperature conditions (i.e., warm growing seasons) (Sage, 1999). Globally, C_4 photosynthesis makes up ca. 25% of terrestrial net primary productivity. CAM plants can be found in some ecosystems, but they are not abundant in many soil carbonate-forming settings.

Figure 5 The $\delta^{18}\text{O}_{\text{cc}}$ (observed) (data from Cerling and Quade (1993), Quade et al. (1989b), and unpublished data) vs. predicted $\delta^{18}\text{O}_{\text{cc}}$ values based on local mean annual temperature and $\delta^{18}\text{O}_{\text{p}}$ of local rainfall.

C_3 plants dominate anywhere, forest or shrubs dominate over grass, irrespective of setting, and C_3 grasses dominate over C_4 grasses above mean monthly temperatures for the warmest month of $\sim 22^\circ\text{C}$ (Collatz et al., 1998). The temperature threshold favoring C_4 grasses may have been higher in the past if pCO_2 was higher (Collatz et al., 1998) and may have been lower during glacial episodes when pCO_2 was lower. Other C_4 plants include a few herbaceous species and saltbush, very common in high desert settings. C_4 grasses include several biochemical variants, termed NAD malic enzyme (NAD-ME), NADP malic enzyme (NADP-ME), and phosphoenolpyruvate (PCK). All these variants have distinct $\delta^{13}\text{C}$ values. The proportion of NAD-ME and PCK variant grasses increases with decreasing rainfall and tends to dominate areas where most soil carbonate forms. $\delta^{13}\text{C}$ values of NAD-ME and PCK variant grasses average $-13.8 \pm 1.4\text{‰}$ today, based on one compilation of data ($n=105$) presented in Cerling et al. (2003) for East Africa. To reconstruct past vegetation, these isotopic averages must be increased by 1.5‰ due to fossil fuel burning (the Suess effect; Friedli et al. (1986)). As a result, prior to 1850, pure C_3 biomass in the drier areas is assumed to have averaged $-25.5 \pm 1.3\text{‰}$ ($-27.0 \pm 1.5\text{‰}$) in $\delta^{13}\text{C}$ (VPDB) prior to 1850, and $-11.8 \pm 1.4\text{‰}$ for pure C_4 plants.

Soil Carbonate Formation and the Soil Diffusion Model

Some early models (e.g., Salomans et al. (1978)) of soil carbonate formation invoked the simple stoichiometry of Eqn [1] to suggest that half the C in solution as HCO_3^- derives from plant-derived CO_2 and half from dissolution of antecedent CaCO_3 such as marine limestone. We now know this view to

be incorrect for soils because it fails to take into account isotopic equilibrium considerations in addition to chemical ones. Two key features of soils – abundant CO_2 produced by plants compared to the small amount of C in soil carbonate, and slow dewatering rates in soils – ensure that soil carbonate undergoes continuous, open-system exchange with a large, isotopically unchanging plant CO_2 reservoir. The pore space of soils contains high concentrations (up to 10 000 ppm V) of CO_2 , the result of root respiration and tissue decay of plants. At deep soil levels, this plant CO_2 reservoir is much larger than any potential contribution from the atmosphere (270 ppm V) or from dissolution of limestone from parent material, typically added at the rate of $\sim 0.005 \text{ mmol m}^{-2} \text{ h}^{-1}$. Another critical feature of soils, particularly drier soils, is that they tend to dewater slowly in the days to weeks after a rainfall event. The long dewatering times ($> \text{day}$) of most soils greatly exceed the chemical rate constants of carbonate reactions (seconds to minutes) between carbon species (e.g., Dulinski and Rozanski (1990)). These considerations make it likely that carbon-isotopic equilibrium is maintained between carbon species during soil carbonate formation.

Plant-derived CO_2 – and hence the local proportions of C_3 to C_4 plants growing at the soil surface – can therefore be predicted to determine the $\delta^{13}\text{C}$ value ($\delta^{13}\text{C}_{\text{cc}}$) of carbonate found deep ($> 50 \text{ cm}$) in soils, where plant-derived soil CO_2 is more concentrated. Shallow in soils, plant-derived CO_2 mixes with atmospheric CO_2 , and the proportion of C_3 to C_4 plants cannot be calculated from soil $\delta^{13}\text{C}_{\text{cc}}$ values. For this reason, it is essential to obtain soil carbonate at depth, generally $> 50 \text{ cm}$, as discussed below.

The one-dimensional soil diffusion model presented in Cerling and Quade (1993), and modified in Davidson (1995), provides the quantitative framework for interpretation

of soil-carbonate-isotopic results. These studies show that at steady state, soil CO₂ concentration varies with depth according to:

$$C_s = \frac{k^2 \phi_s^0}{D_s} (1 - e^{-z/k}) + C_a \quad [3]$$

where D_s = the diffusion coefficient of CO₂ in soils (in cm² s⁻¹); C_s = soil CO₂ concentration (in mmol cm⁻³); C_a = atmospheric CO₂ concentration (in mmol cm⁻³); k = the characteristic production depth (cm) of CO₂ in soils, typically 20–25 cm; z = depth (cm); ϕ_s^0 = CO₂ is the production rate at the soil surface ($z=0$) (in mmol cm⁻² s⁻¹); and assuming several boundary conditions, including $C_s = C_a$ at $z=0$ and $dC/dz=0$ at some specified depth L .

Determination of C_s contributes to estimation of the average $\delta^{13}\text{C}$ value of some mixture of C_3 and C_4 plants growing at a soil site ($\delta^{13}\text{C}_{\text{plant}}$), using the approximation presented in Davidson (1995) but solved in terms of $\delta^{13}\text{C}_{\text{plant}}$:

$$\delta^{13}\text{C}_{\text{plant}} = \frac{\delta^{13}\text{C}_s - 4.4 - \delta^{13}\text{C}_a R(z) + 4.4 R(z)}{1.0044(1 - R(z))} \quad [4]$$

where $\delta^{13}\text{C}_s$ and $\delta^{13}\text{C}_a$ are the $\delta^{13}\text{C}$ values of soil CO₂ and air, respectively, and $R(z) = C_a/C_s$ at the depth of sampling z . This equation subsumes the effects of kinetic enrichment in ¹³C of soil CO₂ during diffusion. This sets up a temperature-independent enrichment of 4.2–4.4‰ CO₂ in the soil with respect to the CO₂ flux leaving the soil (Davidson, 1995). This enrichment factor has been observed empirically (Cerling and Quade (1993) and can be calculated using the Stefan–Maxwell equation applied to CO₂ diffusing through air. At isotopic equilibrium, soil carbonate will be enriched in ¹³C with respect to soil CO₂ by 9–12‰, depending on temperature (25–0 °C). The $\delta^{13}\text{C}_s$ values required to solve for $\delta^{13}\text{C}_{\text{plant}}$ in Eqn [4] can be obtained from the $\delta^{13}\text{C}$ value of soil carbonate ($\delta^{13}\text{C}_{\text{cc}}$):

$$\delta^{13}\text{C}_s = \frac{(\delta^{13}\text{C}_{\text{cc}} + 1000)}{\left(\frac{11.98(\pm 0.13) - 0.12(\pm 0.1)T}{1,000} + 1\right)} - 1000 \quad [5]$$

where $11.98(\pm 0.13) - 0.12(\pm 0.1)T$ expresses the temperature-dependent (T = temperature in °C) enrichment factor between calcite and gaseous CO₂ (Romanek et al., 1992). Inspection of this equation shows that the fractionation factor is not strongly sensitive temperature, with a slope of $\sim 0.12\text{‰ } ^\circ\text{C}^{-1}$.

Substitution of Eqn [5] into Eqn [4] allows $\delta^{13}\text{C}_{\text{plant}}$ to be calculated from $\delta^{13}\text{C}_{\text{cc}}$. The fraction C_4 biomass that once grew on the landscape can in turn be calculated from:

$$\text{fraction } C_4 \text{ biomass} = (\delta^{13}\text{C}_{\text{plant}} - \delta^{13}\text{C}_{\text{C3}}) / (\delta^{13}\text{C}_{\text{C4}} - \delta^{13}\text{C}_{\text{C3}}) \quad [6]$$

where $\delta^{13}\text{C}_{\text{C3}}$ and $\delta^{13}\text{C}_{\text{C4}}$ refer to the average, preindustrial carbon isotopic values of C_3 and C_4 plants, respectively.

In summary, where soil respiration rates are high ($>3\text{--}5 \text{ mmol m}^{-2} \text{ hr}^{-1}$) and for low atmospheric CO₂ concentrations ($<500 \text{ ppmV}$), the isotopic composition of soil carbonate should differ from that of coexisting plant cover by about 13–16‰ (gray-shaded zone, Figure 6). This difference ($\Delta_{\text{cc-om}} = \delta^{13}\text{C}_{\text{cc}} - \delta^{13}\text{C}_{\text{om}}$, where the subscript ‘om’ denotes

soil organic matter) involves both equilibrium fractionation between CaCO₃ and CO₂ of 9–12‰, and kinetic diffusion effects of $\sim 4.4\text{‰}$ (Figure 1). This difference is observed in modern soils with moderate to high respiration rates, verifying the general validity of the model (Figure 6). Where respiration rates are lower, such as in deserts, $\Delta_{\text{cc-om}}$ 13–16‰, as observed from a sampling of soils from the Atacama Desert (Figure 6).

Long-Term Records of Climate Change from Nonlacustrine Calcites

Devils Hole

The long isotopic records from Devils Hole archive $\sim 500 \text{ ka}$ of climate change in southern Nevada. The best-known groundwater calcite records in the region come from two cores obtained by scuba divers at Devils Hole. DH-2 spans 50–310 ka BP and DH-11 50–550 ka BP (Figure 7(a); Winograd et al., 1992), based on multiple alpha and TIMS U-series dates from both cores. Neither record has any apparent depositional hiatuses. Dates from the cores lag climatic events by the time required for water to travel from the recharge area to Devils Hole. Thus, dates on laminated calcite (Figure 3) from Devils Hole represent minimum ages (by $<10 \text{ ka}$) for the recorded climate events.

$\delta^{18}\text{O}_{\text{cc}}$ (SMOW) values from Devils Hole fluctuate between +13.05 and +15.75‰ and display the same sawtooth pattern as marine benthic foram $\delta^{18}\text{O}_{\text{c}}$ records over the same timespan (Figure 7(b)). Overall, the similarity in the form of the $\delta^{18}\text{O}_{\text{c}}$ curve from the Devils Hole record to marine (viewed as a proxy for ice volume changes) and ice records such as Vostok (viewed as a proxy for Antarctic air temperature) is striking.

How is the $\delta^{18}\text{O}_{\text{c}}$ record from Devils Hole being interpreted? The Devils Hole flow system is large ($\sim 12,000 \text{ km}^2$) and receives most of its recharge as winter/spring moisture in the Spring and Sheep mountains $>30 \text{ km}$ away. Mixing and additions of water from such a large recharge area dampen out short-term variations, but preserve them at a longer ($\geq 1 \text{ yr}$) scale (Winograd et al., 1992). The temperature of formation of the calcite has likely remained constant due to the deep circulation of water and the large volume of the flow system. The temperature of the water (25–35 °C) is low enough and the volume of water large enough that changes in primary $\delta^{18}\text{O}_{\text{p}}$ due to water–rock interaction are negligible. Thus, Winograd et al. (1992) have suggested that the main determinant of $\delta^{18}\text{O}_{\text{cc}}$ in the Devils Hole records is the value of $\delta^{18}\text{O}_{\text{p}}$ falling mainly in winter and spring on the recharge area to the Devils Hole. The $\delta^{18}\text{O}_{\text{p}}$ value is in turn determined by $\Delta\delta^{18}\text{O}_{\text{seawater}}$ and by changes in the average winter/spring temperature in cloud masses arriving over the recharge area.

The one feature of the Devils Hole record that has sparked great controversy is the dating of glacial terminations II and III at 140 ± 3 and $253 \pm 3 \times 10^3 \text{ yr BP}$ (2σ), respectively. These are minimum age estimates because of the time lag in the Devils Hole record mentioned before. In the orbitally tuned SPECMAP records, these same terminations date to 128 ± 3 and $244 \pm 3 \times 10^3 \text{ yr BP}$, respectively (Figure 7(c)). The offset of $\geq 9 \text{ ka}$ between age estimates for the terminations is important and challenges the widely held view that changes in the Earth’s orbital parameters drive the Ice Ages. For example, the

Figure 6 The $\delta^{13}\text{C}$ (VPDB) value of soil organic matter vs. that of coexisting soil carbonate. The shaded zone denotes $\Delta_{\text{cc-om}}$ ($= \delta^{13}\text{C}_{\text{cc}} - \delta^{13}\text{C}_{\text{om}}$) values of 13.4–16.4‰ predicted by the soil diffusion model of Cerling and Quade (1993), and observed in most modern soils with moderate to high respiration rates (solid circles). Most values in which $\Delta_{\text{cc-om}}$ 13–16‰ are produced in soils with low respiration rates, as exemplified by sampling of soils from the Atacama Desert (open squares).

orbitally tuned date of $128 \pm 3 \times 10^3$ yr BP for termination II from SPECMAP coincides with a pronounced summer insolation maximum at $128 \pm 1 \times 10^3$ yr BP for the Northern Hemisphere (Figures 7(b) and (c)), strongly supporting a causal link between maximum summer heating in the Northern Hemisphere and ice-sheet retreat. If, however, the Devils Hole chronology is correct, then the linkage between orbital forcing and waxing and waning of glaciation is not so straightforward.

The central question is whether the Devils Hole $\delta^{18}\text{O}_\text{c}$ record represents a regional versus more global record of temperature change. Winograd et al. (1992) have convincingly argued that local air temperature in the recharge area is the dominant control on the $\delta^{18}\text{O}_\text{c}$ value on the Devils Hole record. However, Herbert et al. (2001) contend that changes in air temperature in the region have not changed in phase with average global air temperature. The basis for this is their paleotemperature estimates spanning multiple glacial and interglacial cycles using unsaturated alkenones from marine sediments off the west coast of North America. The whole issue of how globally representative the Devils Hole record is remains unclear, and awaits, in part, development of well-dated groundwater calcite and speleothem records outside of southwestern North America.

The Global Neogene and Pleistocene Paleosol Record

A number of paleosol isotopic records spanning the Neogene have been developed over the past 15 yr that show dramatic environmental change globally. The shift in $\delta^{18}\text{O}$ values must be related to a global climate change, probably aridification. The shift in $\delta^{13}\text{C}$ values reflects a largely concurrent expansion in C_4 grasses at the expense of C_3 grasses, shrubs, and trees. Within the Pleistocene, however, change in C_4 biomass has been conservative globally except in East Africa, where grasslands expanded significantly, possibly influencing the evolution of the genus *Homo*.

$\delta^{18}\text{O}$ record

Most of the oxygen-isotope records from soil carbonates show gradual (Argentina, Latorre et al. (1997); Greece/Turkey, Quade et al. (1994)) to sharp (Pakistan, Quade et al. (1989a); Nepal, Quade et al. (1995); Africa, Cerling (1992), Quade and Levin (in review)) increases in $\delta^{18}\text{O}_{\text{cc}}$ values starting in the late Miocene to early Pliocene (8–4 Ma) (Figure 8). Only the North American (Fox and Koch, 2004) soil carbonate record shows no increases over the late Neogene.

Figure 7 (a) $\delta^{18}\text{O}$ (SMOW) values of a calcite from Devils Hole (Winograd et al., 1992); (b) stacked benthic forams from SPECMAP (Imbrie et al., 1984); and (c) June insolation in W m^{-2} for 60°N (Berger and Loutre, 1991).

The largely global increase in $\delta^{18}\text{O}_{\text{cc}}$ values must reflect important changes in global climate. The shift is too large (3–5‰) and the wrong sign to be explained by temperature declines through the Neogene. As was discussed previously the slope of the theoretical and observed temperature– $\delta^{18}\text{O}_{\text{cc}}$ relationship in modern ‘temperate’ soil carbonate is $+0.44\text{‰ C}^{-1}$. The increase in $\delta^{18}\text{O}_{\text{seawater}}$ is the right sign but far too small ($<1.0\text{‰}$) to explain the increases in $\delta^{18}\text{O}_{\text{cc}}$ values. At mid- to high latitudes, this leaves increased soil water evaporation as the dominant cause for increases in $\delta^{18}\text{O}_{\text{cc}}$ values. At lower latitudes, decreases in rainfall amount also contributed to the increase in $\delta^{18}\text{O}_{\text{cc}}$ values, as well as increased soil water evaporation (Quade and Levin, in review).

$\delta^{13}\text{C}$ record

Most of the carbon-isotope records from soil carbonate show gradual (Argentina, Latorre et al. (1997)) to sharp (Pakistan,

Quade et al. (1989a); Nepal, Quade et al. (1995); Africa, Cerling et al. (1992), Quade and Levin (in review)) increases in $\delta^{13}\text{C}$ values starting in the late Miocene (8–6 Ma) (Figure 9). Others show more modest increases (North America, Fox and Koch (2004)), starting later, in the early Pliocene. One record – the only long record from a Mediterranean (winter rainfall-dominated) climate – shows no appreciable shift through the Neogene (Quade et al., 1994) (Figure 9).

Most of the increase in $\delta^{13}\text{C}$ values can be attributed to increases in C_4 grasses, although the contribution by lower respiration rates to higher $\delta^{13}\text{C}$ values has not been unequivocally excluded in some records (Latorre et al., 1997; Fox and Koch, 2004). The lack of change in $\delta^{13}\text{C}$ values from the eastern Mediterranean record accords with the lack of C_4 plants in that region today. In some areas, the ecologic shift involved a change in life form: C_4 grasses replaced C_3 forest (e.g., Nepal, Quade et al. (1995)). In others, photosynthetic pathway but not life form

Figure 8 Global Neogene trends in $\delta^{18}\text{O}_{\text{oc}}$ values from (a) Pakistan (Quade et al., 1989a and unpublished data); (b) East Africa (Quade and Levin, in review); (c) Argentina (Latorre et al., 1997); (d) Greece and Turkey (Quade et al., 1994); (e) North America (Fox and Koch, 2004; data courtesy of D. Fox).

changed: C_4 grasses apparently replaced a substantial fraction of C_3 grasses (e.g., North America: Fox and Koch (2004)). Cerling et al. (1997) observed similar increases over the late Neogene in the diet of large herbivores, attributed to increases in the dietary intake of C_4 grasses.

The cause of this dramatic and largely global change in plant cover remains unclear. The C_4 expansion might be explained by a decline in $p\text{CO}_2$ globally, one of the environmental conditions that favors C_4 metabolism (Cerling et al., 1997). However, there is no evidence of decline in $p\text{CO}_2$ over this period (Pagani et al., 1999). Increased moisture stress, like $p\text{CO}_2$ decline, would also favor C_4 plant expansion. This explanation is supported by the clear increases over the same timespan in $\delta^{18}\text{O}_{\text{oc}}$ values, a trend we have already linked to aridification. The main weakness of this explanation is that it does not explain why C_4 metabolism did not expand earlier. Although more prevalent in the late Neogene, semiarid environments must have been present in the pre-late Miocene. C_4 plants are favored by fire, and an increase in fire frequency would support the expansion of C_4 biomass. This, too, is a hypothesis worth exploring.

The global carbon-isotope record from paleosols shows little change over the Pleistocene. A significant exception to this is the sharp increase in $\delta^{13}\text{C}_{\text{cc}}$ values observed from East Africa (Figure 9(b); summarized in Quade and Levin (in review)). At many study sites, $\delta^{13}\text{C}_{\text{cc}}$ values increase for the first time above -2‰ during the Pleistocene, denoting the

appearance of savanna grasslands ($>80\%$ C_4 biomass) so characteristic of the region today. The pattern of expansion is uneven temporally and geographically, commencing as early as the late Miocene at Lothagam, but much later, in the 2.7–1.0 Ma timespan, at most other sites. Many researchers draw the possible connection between this expansion of savanna ecosystems and the development of the genus *Homo* in Africa starting sometime in the latest Pliocene (see review of Klein (1995)). The Pleistocene-age increase in $\delta^{13}\text{C}$ values in East Africa is embedded in a local, longer-term trend toward higher $\delta^{18}\text{O}$ values, again a pattern we attribute to aridification.

The impact on regional vegetation and climate during shifts from glaciations to interglaciations is also apparent in a number of isotopic records from paleosols from the Pleistocene. As just two examples, glacial-age soil carbonates from the Wind River Mountains of Wyoming, USA (Amundson et al., 1996) yielded $\delta^{18}\text{O}_{\text{oc}}$ values significantly higher than modern soil carbonate values. This was interpreted to be the result of a combination of colder temperatures and the increased contribution of high $\delta^{18}\text{O}_{\text{oc}}$ waters from the Gulf of Mexico. In the Great Basin, western USA, $\delta^{13}\text{C}_{\text{cc}}$ values decreased during glaciations, as C_3 -dominated vegetation at higher elevations today was displaced downward (Quade et al., 1990). Recent advances in $^{230}\text{Th}/\text{U}$ dating of individual laminae in desert soil carbonates (e.g. Sharp et al., 2003) should lead to much more extensive use of soil isotopic archives in shorter-term (10^4 – 10^5 yr) paleoclimate reconstruction.

Lake Sediments

Introduction

Lakes are widely distributed across the continents and are found in climatic zones ranging from Antarctica to the tropics and from moist to relatively arid environments. Lacustrine sediments are important archives of climatic and environmental change. Their wide spatial distribution enables the study of the regional impact of global climate change in a variety of climatic regimes with high geographic and temporal resolution. Lakes precipitating authigenic carbonate or containing carbonate in the form of biogenic shells have been subjects of considerable research since the pioneering studies in the early 1970s (e.g., [Stuiver, 1970](#)). Because of the relative ease of analysis and the development of automated analytical systems, isotope studies of bulk lacustrine carbonates have become common. However, the extraction of quantitative climatic and paleoenvironmental information from bulk carbonate records is not straightforward or simple. The main difficulties in interpreting oxygen isotope records are related to three main factors:

1. Bulk carbonates in lakes represent a mixture of particles with different origins;
2. The isotopic composition of the precipitated calcium carbonate is dependent on the water temperature and the isotopic composition of the lake water, and, thus, on the hydrological balance of a lake; and
3. Biological activity in the lake, by influencing the carbonate chemistry, may influence the mechanisms, water depth and timing of carbonate precipitation. In particular, if the hydrology of the lake is not well understood, a quantitative reconstruction of climate is prone to large errors.

Global Spatial- and Age-Distribution of Carbonate-Precipitating Lakes

Carbonate-precipitating lakes and paleolakes are found on all continents, at various latitudes and altitudes. The main control on the presence of carbonate in a lake is the composition of the bedrock. Significant calcium carbonate precipitation in the water column is observed only in lakes that have a large part of the catchment consisting of calcium carbonate-rich rocks, which supply most of the calcium and carbonate ions through weathering reactions. Lakes within catchments dominated by silicate rocks are normally devoid of carbonates. Calcium carbonate supersaturation in the bottom waters and the sediments is also necessary to avoid postdepositional dissolution of calcite, which is promoted by CO₂ production related to organic matter decomposition.

The spatial distribution and age of lakes is dependent on their origin. Lakes of glacial origin are very common in formerly glaciated areas of Europe, Asia, and the Americas.

Although some lakes may have originated in the Tertiary (e.g., the lakes of the insubric region in northern Italy and Switzerland) most of the sediments preserved, or accessible to sampling, in these lakes are younger than the Last Glacial Maximum, about 18 000 years before present. Older sediments were either removed by glacial erosion during the glacial advances or are compacted and present at sediment depths that are reachable only by deep drilling. Lakes of tectonic origin are globally less numerous than glacial lakes, but they are a prominent feature for their size and permanence, and have provided some of the longest records of continental climate. Lakes of tectonic origin include all of the major lakes in Africa; the Aral and Caspian seas, Lake Baikal, Lake Van and the Dead Sea (and its paleolake equivalent Lake Lisan) in Eurasia; Lake Titicaca in South America; the Great Salt Lake, Utah, and its paleolake equivalent Lake Bonneville and Pyramid Lake, Nevada in North America. Crater lakes, which also have provided important long paleoclimatic records, are often devoid of carbonates due to the chemistry of the waters.

Sampling of Lacustrine Sediments

Paleoclimatic studies on lacustrine sediments are mostly carried out on cores obtained by various platforms and coring devices ranging from handheld gravity cores to complex drilling platforms. For a review of coring devices, see [Glew et al. \(2001\)](#). Sedimentation rates, and thus the length of cores required for long paleoclimatic records and the sampling resolution achievable, vary dramatically in lakes. In smaller peri-alpine lakes of glacial origin, sediment accumulation rates are in the range of 0.5–5 mm year⁻¹. Typical length of cores are 1–2 m for simple handheld gravity cores, which allow studies of the last few hundred to a few thousand years in very small lakes with low sedimentation rates. For the recovery of longer sediment sequences of up to 10–20 m, larger platform systems have to be used. A large drilling platform that is managed by the International Continental Drilling Program (<http://www.icdp-online.org>) has been operational since 1998 and has allowed the recovery of climate records from lakes reaching back 1 My.

Nature of Carbonate in Lacustrine Sediments

The carbonate fraction of lacustrine sediments can contain particles of multiple *in situ* origins:

1. an inorganically precipitated carbonate,
2. a biogenic fraction formed in the water column, and
3. a fraction which can be formed by diagenesis after the deposition of the sediments.

In addition, because carbonate-precipitating, hard-water lakes are found in catchments composed, at least partially, of carbonate bedrocks, some fraction of the carbonate will be of detrital origin. For a quantitative interpretation of the isotopic signal, the origin of the carbonate particles has to be determined by X-ray diffractometry and by petrographic examination with light- or electron microscopy. Only the authigenic particles (Figure 1) formed in the surface waters carry relevant isotopic information for paleoclimatic reconstruction, and, thus, they should be the only or at least the dominant fraction of the sediments used to obtain meaningful information from bulk carbonate isotope analyses.

Carbonate Precipitation in Mid- to High-Latitude, Hard-Water Lakes

Carbonate precipitation in deep, hydrologically open, hard-water lakes is induced by increases in pH and carbonate ion concentration related to the utilization of aqueous CO_2 by photosynthetic organisms, which increases calcium carbonate

Lake Albano, Italy

Lake Butrinti, Albania

supersaturation (Kelts and Hsu, 1978). An active role of cyanobacterial picoplankton in carbonate precipitation has been postulated by Thompson et al. (1997) and Ditttrich et al. (2004), and also has to be considered for the understanding of carbon and oxygen isotope geochemistry of carbonates. Carbonate precipitation in mid- to high-latitude lakes is commonly limited to a period comprised between early spring and late autumn, when higher temperatures and light levels stimulate algal production. This period follows the annual recharging of the surface waters with essential nutrients as a result of the winter overturn of the water column. The isotopic composition of carbonate precipitate, therefore, predominantly reflects spring and summer conditions, whereas the sedimentation in the late fall and winter months consists predominantly of clastic material and organic matter. If the bottom waters of a lake are at least temporarily anoxic, the rhythmic sedimentation induced by the annual productivity cycle can be preserved in the sediment in the form of chemical varves of alternating white summer and dark winter layers (Figure 2). The presence of an annual lamination allows the accurate dating of sedimentary sequences by varve-counting. In addition, it facilitates the acquisition of paleoenvironmental records at annual or even at semiannual resolution (e.g., Teranes et al., 1999b). Even in this case, however, it has to be kept in mind that the residence time of the water in the catchment area and the lake itself is the limiting factor for the true temporal resolution of a sedimentary record.

The precipitation of calcium carbonate occurs close to the surface of the lake, where the biological activity is most intense. The time in the season and the water depth where calcium carbonate precipitates may vary from year to year, potentially creating spurious variations in the isotopic signatures of the carbonates. Large temperature gradients of up to 15°C in the top 20 m of the water column are common, and the temperature range at the lake surface between spring and summer can reach $10\text{--}15^\circ$ (e.g., Livingstone and Lotter, 1999; Teranes et al., 1999a). Because the precipitation of carbonate is dependent on the biological activity, oxygen isotope records from lakes, which have undergone strong changes in trophic level and productivity, have to be considered with caution. Possible effects of eutrophication on oxygen isotope records have been critically discussed, for example, Gat and Lister (1995). Fronval et al. (1995) have shown that carbonate precipitation can occur in isotopic disequilibrium with the water under strongly eutrophic conditions, leading to a negative isotope shift in $\delta^{18}\text{O}$. Teranes et al. (1999a), on the other hand, have shown in eutrophic Baldeggersee, Switzerland, that, although isotopic disequilibrium is observed during events of rapid calcite precipitation, a large part of the calcite can precipitate close to equilibrium.

Carbonate Precipitation in Saline and Closed-Basin Lakes

In hydrologically closed lakes and in arid regions, carbonates are precipitated mainly as a consequence of a negative water balance. In these lakes, the effects of biological activity are less important because the main driving force for carbonate precipitation is the increase in Ca^{2+} and CO_3^{2-} concentrations related to evaporation. In contrast to hard-water lakes where the mineralogy of the authigenic carbonates is dominantly low

Bernasconi & McKenzie

Figure 2 Photo of a gravity core collected from 130 m depth in Lake Zürich, Switzerland. For the last 100 years, a clear annual lamination is visible in the sediments. The light layers are composed mainly of authigenic calcite formed in the water column in spring to late summer. The dark layers are rich in diatoms, organic matter and clays and represent autumn and winter sedimentation. The thick layers at 25–29 cm and 33–34 cm are fine grained redeposited sediments derived from slope instabilities. The bottom of the core shows homogeneous carbonate-rich sediment deposited before significant eutrophication led to the preservation of the annual lamination.

magnesium calcite, a larger variety of carbonate minerals are found in saline lakes, including high magnesium calcite, aragonite, and dolomite, as well as more soluble Na–Ca carbonates such as gaylussite and trona (see e.g., Talbot, 1990). The mineralogy is related to the degree of salinity of the water

and provides an independent way to estimate evaporation levels. For example, in Lake Van, Turkey, the Mg content of calcite increases with increasing salinity and can be used in conjunction with isotopes to constrain evaporation/precipitation ratios (Wick et al., 2003). Isotope records from strongly evaporative soda lakes are relatively rare, due mainly to concerns related to recrystallization of the very soluble carbonates. However, there is potential to extract useful climatic information even from such highly soluble carbonates (Bernasconi et al., 1997).

Isotopic Composition of Lacustrine Carbonate

In paleoclimatic studies, the stratigraphic variation of the oxygen isotope composition of carbonates is used to reconstruct changes in temperature and/or oxygen isotope composition of the lake water. Both these parameters depend on local climate variations and on the hydrologic characteristics of the lake. Before quantitative inferences on climate can be made, the main controls on the oxygen isotopic composition of the lake water have to be evaluated, as each lake shows a different response to climatic forcing. When the hydrology of the lake is known, more precise climate information can be extracted from the oxygen isotope record.

The carbon isotope composition of carbonates does not contain direct climatic information, mainly because carbon isotope fractionation between dissolved inorganic carbon and calcite is only very weakly temperature dependent. The $\delta^{13}\text{C}$ value of carbonates mainly reflects changes in the inputs of dissolved inorganic carbon from the catchment area and exchange with the atmosphere. Moreover, it is strongly influenced by biological activity within the lake, leading to the development of surface-to-bottom water carbon-isotope gradient, similar to that found in the marine environment (McKenzie, 1985). Essentially, there is a transfer of ^{12}C from the surface to the deeper waters by a photosynthesis–respiration pathway, and the degree of this photosynthetic activity is reflected in the $\delta^{13}\text{C}$ value of the dissolved inorganic carbon and incorporated into the carbonate precipitate (Figure 3). Thus, the carbon isotope record archived in lacustrine carbonates documents changes in the paleoproductivity of lakes and, because of the intrinsic link between the inorganic carbonate precipitate and the associated organic carbon, information about the dominant photosynthetic mechanism (CO_2 vs. HCO_3^- utilization) can be gained (Hollander and McKenzie, 1991; Teranes and Bernasconi, 2005).

In addition, the carbon isotope composition of the carbonates provides important information on changes in the catchment and within the lakes, which can be used to better interpret the oxygen isotope signal. For example, the $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values for lacustrine carbonates from many closed-basin lakes have been found to covary (Talbot, 1990 and references therein). As this $\delta^{13}\text{C}$ – $\delta^{18}\text{O}$ covariance is absent or weak in hydrological open lakes, it can be a useful indicator to interpret the open/closed history of a paleo-lake system. Li and Ku (1997) have evaluated the causal mechanism for the observed $\delta^{13}\text{C}$ – $\delta^{18}\text{O}$ covariance in the closed-basin lake setting and attribute its occurrence and varying intensity to a number

Figure 3 Carbon isotope profiles in the water column of lake Lugano in different months. Note the constant composition in winter after the water column has mixed during spring and summer there is a progressive enrichment in ^{13}C in the photic zone due to the preferential assimilation of ^{12}C by the algae. In contrast, in the bottom waters the oxidation of organic matter leads to a decrease in $\delta^{13}\text{C}$ of the dissolved inorganic carbon. Data from Lehmann et al. (2004).

of factors, including size of lake, duration of hydrological closure, vapor exchange, and lake productivity and alkalinity.

Oxygen Isotope Composition of Lake Water and Its Relation to Climate and Local Hydrology

Lakes are dynamic systems linked to the hydrological cycle via surface and subsurface inflow and outflow and via direct precipitation and evaporation from the lake surface. The factors controlling the oxygen isotope composition of lake waters are schematically summarized in Figure 4. Mathematically, the isotopic water balance of a lake can be expressed as

$$V_{\text{lake}} \delta^{18}\text{O}_{\text{lake}} = \sum I \delta^{18}\text{O}_I + P \delta^{18}\text{O}_P - \sum O \delta^{18}\text{O}_{\text{lake}} - E \delta^{18}\text{O}_E$$

where V is the volume of the lake, $\delta^{18}\text{O}$ is the oxygen isotopic composition of the various components, I is the inputs (rivers and surface runoff, groundwater input), P is direct precipitation on the lake, O is the output (surface and subsurface output), and E is the evaporation. Note that the surface and groundwater outputs have the same isotopic composition as the lake water. The only output component which imparts a fractionation on the isotopic composition of waters is evaporation. Thus, this factor is the most important parameter modifying the oxygen isotope composition of a lake besides the mixing of the various inputs. In hydrologically open basins, the $\delta^{18}\text{O}$ of lake water depends predominantly on the relative

Figure 4 Schematic diagram of the main factors controlling the isotope composition of lake waters.

fluxes and $\delta^{18}\text{O}$ values of the inputs with more or less important modification induced by evaporation processes. In closed lake basins, where there is no surface or subsurface output ($O=0$), the water balance of the lake and its isotopic composition are determined by the difference between evaporation and precipitation in the lake and the inputs in the catchment.

The $\delta^{18}\text{O}$ of the lake water, as it is recorded by sedimentary carbonates formed in the surface waters, is additionally influenced by the pattern of vertical mixing of the lake. In monomictic lakes during the stratification period in the summer when most of the carbonate precipitates, the surface waters becomes enriched in ^{18}O due to the preferential removal of ^{16}O with evaporation. Thus, the carbonate will not necessarily reflect the bulk oxygen isotope composition of the lake but will show a variably enriched composition which is dependent on the evaporation intensity (Figure 5). This enrichment can be significant (up to a few ‰) and introduces an additional uncertainty factor in the interpretation of carbonate oxygen isotope records.

The oxygen isotopic composition of precipitation is dependent on the air temperature (Dansgaard, 1964; Rozanski et al., 1993), the source of moisture (i.e., large scale atmospheric circulation), and the seasonal distribution of precipitation (Rozanski et al., 1993). Dansgaard (1964) first described the temperature dependence of the oxygen isotope composition of precipitation. He noted a global relationship of $0.69\text{‰}^\circ\text{C}^{-1}$ for mid- and high northern latitudes, with stronger variations depending on the location. The more recent compilation of Rozanski et al. (1993) provides an excellent updated analysis of the IAEA/GNIP database (International Atomic Energy Agency Global Network of Isotopes in Precipitation <http://www-naweb.iaea.org/napc/ih>). This database is an irreplaceable tool for the calibration of the modern relationship at many locations around the world, which, in turn, can be used for the calibration and interpretation of the paleo-records of precipitation.

In a recent study, Kohn and Welker (2005) have reanalyzed data from four stations in the United States and concluded that the oxygen isotope-mean temperature correlation can be improved, showing a slope always close to $0.55\text{‰}^\circ\text{C}^{-1}$, if the isotope data are correlated with the average temperature on the days when precipitation occurs, rather than the overall average temperature. This effect can be easily understood if one considers that, in summer, the average temperature on

Figure 5 Oxygen isotope composition of lake waters in a water-column profile from Lake Lugano, Switzerland for three different months in 1994–1995. Note the increase in the $\delta^{18}\text{O}$ values of up to 1.5‰ during summer stratification and the homogeneous composition of the water column in March after the lake has mixed.

the days with rain are systematically cooler than days without precipitation, whereas, in winter, the opposite effect is seen (Kohn and Welker, 2005). Thus, the $\delta^{18}\text{O}$ of precipitation most closely reflects a ‘precipitation temperature’ rather than the average yearly or monthly temperature. This adds an additional uncertainty in paleoclimatic reconstructions because, unfortunately, these two temperatures are not well correlated. Changes in moisture source, in the contribution of re-evaporated moisture and seasonal distribution of precipitation also need to be considered. Changes in moisture source or changes in reevaporation along the trajectory of the air mass can change the local temperature/oxygen isotope relationships. Air masses with different sources may have different isotope composition due to the different evaporation source and rain-out history (e.g., Clark and Fritz, 1997, p. 53). An additional important factor is the seasonal distribution of precipitation. In summer, the $\delta^{18}\text{O}$ of precipitation is higher than in winter (e.g., Rozanski et al., 1993). Thus, a switch from more dominant winter to summer precipitation can lead to changes in the $\delta^{18}\text{O}$ of lake water, which could be erroneously interpreted as a temperature change. The effect of changes in atmospheric circulation on lacustrine isotope records has been discussed and holds important potential for developing regional paleoclimate archives (e.g., Hammarlund et al., 2002; Henderson et al. 2010; Hodell et al., 1998; Kirby et al., 2002; McKenzie and Hollander, 1993; Smith and Hollander, 1999; Teranes and McKenzie, 2001).

The above discussion illustrates that, because of the complex nature of the signal, it is virtually impossible to quantitatively reconstruct temperature variations or relative temperature changes without making some important assumptions. For this reason, oxygen isotope studies on lacustrine carbonates should be coupled with other methods and proxies to achieve more precise climate reconstructions. An interesting upcoming new method for temperature reconstructions is the clumped-isotope thermometer (Eiler, 2007; Ghosh et al., 2006). This method is based on the abundance of the ^{13}C – ^{18}O bond in carbonate and allows to determine the temperature of formation of the carbonate independently of the $\delta^{18}\text{O}$ of water. After the temperature is known, it is subsequently possible to determine the $\delta^{18}\text{O}$ of the lake water from the oxygen isotope composition of the carbonate. This method has not been applied to lakes yet. Additional methodologies are palynological or micro-paleontological studies, as well as other novel geochemical proxies such as compound-specific hydrogen isotopes in organic matter (e.g., Huang et al., 2004; Sachs et al., 2009; Sauer et al., 2001). In addition, as suggested by Kohn and Welker (2005), air temperature reconstructions based on the reconstruction of the $\delta^{18}\text{O}$ of precipitation should be validated with modeling efforts conducted using global climate models (GCMs).

Oxygen Isotope Temperature Calculations

Following the discussion of the factors controlling the oxygen isotope composition of lake water, we next consider the factors controlling the oxygen isotope composition of the associated carbonates. These are an indirect archive for the oxygen isotope composition of precipitation and, as such, are an additional filter and source of noise, which has to be understood if quantitative reconstructions of climate change are to be obtained. In particular, the primary question that has to be asked when using oxygen isotope data derived from bulk carbonate in lacustrine sediments is: do they record water temperature or rather the oxygen isotope composition of the water?

The oxygen isotope fractionation between water and calcite has been extensively studied, and a number of paleotemperature equations have been published. In a recent review, Leng and Marshall (2004) proposed to adopt the following modified form of the Kim and O’Neil (1997) calibration:

$$T(^{\circ}\text{C}) = 13.8 - 4.58(\delta_c - \delta_w) + 0.08(\delta_c - \delta_w)^2$$

where δ_c is the oxygen isotope composition of the carbonate with respect to the VPDB standard and δ_w is the oxygen isotope composition of the water with respect to the VSMOW standard (Coplen 1994). The examination of this equation shows that there are two unknowns, the temperature of precipitation and the $\delta^{18}\text{O}$ of the lake water. Thus, for paleoclimate reconstructions, assumptions are necessary to separate these two factors. In the case of tropical to subtropical lakes, even at the scale of glacial to interglacial cycles, the temperature variations at a location are relatively minor, on the order of a couple of degrees centigrade. Thus, the oxygen isotope composition of the carbonate can be interpreted as predominantly a reflection of the $\delta^{18}\text{O}$ of the lake water. Neglecting possible temperature changes will introduce only a minor error in the estimates. In this case, the stratigraphic variations will be dependent

on changes in the water balance, origin of air masses and/or changes in the catchment area (Rosenmeier et al., 2002). As discussed above, in hydrologically open mid- to high-latitude hard-water lakes, carbonate precipitation occurs mainly between April and October, as a consequence of biological activity and increasing temperatures. Thus, possible temperature effects have to be taken into consideration. As shown by Livingstone and Lotter (1999), lake water temperature in the upper epilimnion closely correlates with mean air temperature, therefore, in this case, temperature will influence the oxygen isotope signal in carbonates. An interesting aspect is that increasing average air temperatures would lead to an increase in the $\delta^{18}\text{O}$ of lake water due to the positive correlation between air temperature and $\delta^{18}\text{O}$ of precipitation which is on the order of $0.55\text{‰}\text{°C}^{-1}$ (Kohn and Welker, 2005). At the same time, increasing water temperatures would lead to a decrease in oxygen isotope composition of the calcite because the fractionation between water and calcite decreases with increasing temperature (Kim and O'Neil, 1997), at a rate of approximately $0.2\text{‰}\text{°C}^{-1}$. Thus, the net effect of temperature increase on carbonate isotope composition would be on the order of $0.35\text{‰}\text{°C}^{-1}$. Unfortunately, other factors discussed below, may also play a role in determining the oxygen isotope composition of the carbonate, and only rarely a direct inference of average annual temperature can be made. This approximation has been confirmed in case studies, such as one for Baldeggersee, Switzerland, where, based on an isotope mass-balance model, the $\delta^{18}\text{O}$ /temperature relationship was calculated to be $0.39\text{‰}\text{°C}^{-1}$ (Teranes and McKenzie, 2001).

Environmental Effects (e.g., Vital Effects, pH) on the Oxygen Isotope Composition of Carbonate

Calcite precipitation occurs in lakes only after relatively high levels of supersaturation have been reached (Kelts and Hsu, 1978). Thus, strictly speaking, carbonate precipitation is not an equilibrium process, and the possibility of isotopic disequilibrium has to be taken into consideration. Although most paleoclimatological studies tacitly assume that carbonate precipitation occurs in equilibrium with the water, this has rarely been demonstrated with water column studies. Sediment trap studies in eutrophic lakes indicate that most of the carbonate does precipitate in isotopic equilibrium (Fisher 1996; Teranes et al., 1999a). However, it is not always possible to demonstrate this unambiguously because the water depth at which carbonate precipitation occurs may vary with the trophic level of a lake or with the type of organisms responsible for inducing carbonate precipitation.

The mechanism and water depth of carbonate precipitation are important because the location and timing in the annual cycle of carbonate precipitation influences its isotopic composition. This is a particularly important factor in lakes, as compared to the oceans, because the water column is characterized by strong vertical gradients in temperature and in summer, also, in oxygen isotope composition. In addition, the annual productivity cycle can be variable and produce shifts in the timing of precipitation of carbonates, which can introduce spurious variations in their oxygen isotope composition.

The pH of the lake water is also an important parameter to consider in the interpretation of carbonate records. Recently,

studies pioneered by Zeebe (1999, 2007) have proposed a model of pH dependence of oxygen isotope composition of carbonates, which can be used to explain effects previously attributed to disequilibrium, kinetic fractionations and/or to not always clearly understood 'vital effects.' These studies show that the observed decrease in oxygen isotope composition with the concentration of CO_3^{2-} , first observed by Spero et al. (1996) and commonly considered a 'vital effect' or disequilibrium, can be explained by carbonate precipitation at different pH values. This model is based on the fact that dissolved HCO_3^- has an approximately 7‰ higher $\delta^{18}\text{O}$ than CO_3^{2-} (at 25 °C, Zeebe, 2007). Thus, if carbonate precipitating as calcite contains a mixture of bicarbonate and carbonate, precipitation at higher pH will lead to a progressively lower oxygen isotope composition. This is caused by the higher abundance of CO_3^{2-} with increasing pH. This process is potentially particularly important in lakes because the pH of the surface waters can vary over 2–3 pH units throughout the year. It is also significant that vertical pH gradients are observed in the water column. These gradients are particularly strong during summer when primary productivity is at maximum in concomitance with the stable thermal stratification in the mixolimnion. A pH effect may explain the decrease in $\delta^{18}\text{O}$ observed by Teranes et al. (1999b) in their sediment trap study of Lake Baldegger, Switzerland. A disturbance of the oxygen isotope records of calcite may also be expected when a lake undergoes eutrophication. At higher levels of primary productivity, the pH in the surface waters can be expected to reach higher values. Therefore, some of the negative $\delta^{18}\text{O}$ shifts observed in highly productive lakes may be due to higher average pH related to increased productivity rather than to changes in the $\delta^{18}\text{O}$ of the waters or to a shift to carbonate precipitation later in the summer, when water temperatures are higher.

Quaternary Lacustrine Isotopic Records

Quaternary marine oxygen isotope records show a dominant pattern of change modulated by glacial–interglacial changes in ice volume and temperature, which can be found at most latitudes and longitudes. This clear and reproducible pattern of variation has been used to define a robust chronology, the marine isotope stages, which can be used as an accurate dating tool. In contrast, lacustrine oxygen isotope records are much more dominated by local effects. Therefore, it is not possible to establish a general lacustrine quaternary isotope stratigraphy equivalent to the marine one. Nevertheless, as discussed above, lacustrine isotope records, when compared with marine and other terrestrial archives, provide important climatic constraints. Depending on the type of lake, isotope composition of lacustrine carbonates may reflect changes in average air temperature, seasonal distribution of precipitation, evaporation/precipitation ratio (aridity) or for example changes in atmospheric circulation patterns.

Summary and Conclusions

In spite of the complexities in the interpretation of bulk lacustrine carbonate oxygen isotope values, lacustrine oxygen isotope records are arguably an invaluable source of paleoclimatic

data. The last years have seen major progress in our understanding of the hydrological effects on the oxygen isotope composition of lakes and on the significance and problems related to the interpretation of bulk lacustrine isotope records. The quantitative interpretation of lacustrine oxygen isotope records requires, first of all, a good understanding of the hydrology of the studied lake. Important parameters include a good characterization of the catchment area, which may not be easily determined in karstic areas, where significant underground sources and outflow can occur, and information on the residence time of the water in both the catchment and the lake itself, which controls the temporal resolution of the sedimentary record. In addition, the relationship between $\delta^{18}\text{O}$ of the precipitation in the catchment area and the lake water has to be understood and calibrated. Possible changes in the catchment area through time and its effect on the hydrological and isotopic balance have also to be considered. Soil and vegetation development may change the residence time of the water in the catchment and diversion of tributaries, by natural or anthropogenic causes, may change the size and characteristics of the catchment area and, hence, the isotope composition of the inputs.

Finally, the sediment has to be carefully examined to determine possible disturbances of the primary signal by detrital or authigenic carbonate components of variable origin, which may lead to spurious variations in $\delta^{18}\text{O}$ of the bulk carbonate. Possible effects due to changes in trophic state have to be considered also as a possible complication. This is especially important for lakes strongly affected by anthropogenic or natural eutrophication. Future, in-progress developments include the implementation of isotopes in precipitation in global circulation models, which can be used to evaluate the relative importance of temperature versus changes in atmospheric circulation on the oxygen isotope records. In addition, the robustness of oxygen isotope records needs to be validated with independent records, such as those derived from clumped isotopes, tree rings or compound-specific hydrogen isotopes. In conclusion, there are ongoing efforts to establish stable isotope maps of precipitation for different time slices, using a combination of terrestrial isotope records including lakes. These maps can be used to test and calibrate GCM's to improve our quantitative understanding of paleoclimatic variations.

Introduction

Biogenic carbonates – predominantly calcite and aragonite precipitated by plants and animals in non-marine surface waters – are ubiquitous in Quaternary age deposits. Carbon and oxygen isotope ratios ($\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values) of these materials are routinely used as proxies for climate change. The ultimate utility of these data rests on scientists' ability to calibrate modern analogs, understand biological fractionations or 'vital effects', and use appropriate sampling methods. These materials have the potential for providing detailed data (sub-monthly resolution) for time periods that range from 1 to 50 years in length. This temporal resolution can be used in conjunction with longer term, yet lower temporal resolution, terrestrial isotope records (e.g., ice cores, stalagmites, soil profiles, and lake sediment cores) to examine seasonal variation in temperature, precipitation, vegetation, productivity, and water column stratification.

Equilibrium Precipitation

Isotope geochemists often seek to determine whether CaCO_3 is precipitated in isotopic equilibrium with ambient waters (i.e., the $\delta^{18}\text{O}_{\text{water}}$ and $\delta^{13}\text{C}_{\text{DIC}}$ values). By knowing this relation, it may be possible to determine the temperature or the isotopic composition of waters in which ancient carbonates formed. As with most estimates of this sort, assumptions must be made. Unfortunately, carbonate oxygen isotope thermometry requires knowledge of the $\delta^{18}\text{O}$ value of ambient waters. Conversely, estimates of $\delta^{18}\text{O}_{\text{water}}$ values require knowledge of the temperature at which the carbonate precipitated. To evaluate equilibrium precipitation, the results of numerous experimental and empirical studies must be considered.

Equilibrium $\delta^{18}\text{O}$ values of calcite are most accurately estimated using the $\delta^{18}\text{O}$ value of ambient water, water temperature (in kelvins), and a calcite (low-Mg calcite), the calcite-water fractionation factor (α), and an expression that relates these variables (Friedman and O'Neil, 1977; Kim and O'Neil, 1997).

$$\alpha(\text{CaCO}_3\text{-water}) = \frac{(1000 + \delta^{18}\text{O}_{\text{CaCO}_3(\text{SMOW})})}{(1000 + \delta^{18}\text{O}_{\text{Water}(\text{SMOW})})} \quad [1]$$

$$10^3 \ln \alpha(\text{calcite-water}) = 2.78(10^6/T^2) - 2.89 \quad [2]$$

(Friedman and O'Neil, 1977)

$$10^3 \ln \alpha(\text{calcite-water}) = 18.03(10^3/T) - 32.42 \quad [3]$$

(Kim and O'Neil, 1997)

These values can be corrected for the Mg-content of the calcite (+0.06‰ per mol% MgCO_3 ; Tarutani et al., 1969).

To examine carbonate equilibrium $\delta^{13}\text{C}$ values, it is necessary to know the $\delta^{13}\text{C}$ value of water bicarbonate (HCO_3^-) or the dissolved inorganic carbon ($\delta^{13}\text{C}_{\text{DIC}}$). The calcite- HCO_3^- carbon isotope enrichment factor is +1.0‰ (and is constant from 10 to 40 °C). The aragonite- HCO_3^- enrichment factor is +2.7‰ throughout the same temperatures range (Romanek et al., 1992). Assuming equilibrium precipitation, one can estimate ambient $\delta^{13}\text{C}_{\text{DIC}}$ values by subtracting 1.0 or 2.7‰ from measured calcite and aragonite values. Likewise, aragonite equilibrium $\delta^{13}\text{C}$ values can be estimated by adding the aragonite-calcite enrichment factor to measured calcite $\delta^{13}\text{C}$ values (+1.6‰ of Rubinson and Clayton, 1969; +1.7‰ of Romanek et al., 1992).

The only empirically derived oxygen isotope fractionation factor for freshwater fish otoliths is:

$$10^3 \ln \alpha(\text{aragonite-water}) = 18.56(10^3/T) - 33.49 \quad [4]$$

(Patterson et al., 1993)

The only empirically derived expression describing the oxygen isotope fractionation factor in Unionid aragonite is:

$$10^3 \ln \alpha(\text{aragonite-water}) = 2.559(10^6/T^2) + 0.715 \quad [5]$$

(Dettman et al., 1999)

Equations 4 and 5 have slopes similar to that of Grossman and Ku (1986) for biogenic aragonite:

$$10^3 \ln \alpha(\text{aragonite-water}) = 18.07(10^3/T) - 31.079 \quad [6]$$

(Grossman and Ku, 1986)

'Vital Effects' and Modern Calibration

The most significant impediment to effectively using freshwater biogenic carbonates as climate or environmental proxies is a generally poor understanding of biological fractionation of stable isotopes during formation. 'Vital effects' (Urey et al., 1951) are in many ways a means of categorizing processes that are poorly understood. Numerous studies have examined 'vital effects' in a variety of marine organisms (see these and citations within; corals, Adkins et al., 2003; calcareous algae, Lee and Carpenter, 2001; brachiopods, Carpenter and Lohmann, 1995; Foraminifera, Zeebe, 1999). Common among these studies is a less-than-satisfactory explanation of mechanisms and rates of carbonate precipitation, the incorporation of metabolic CO_2 , and the positive covariance of $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values in many biogenic carbonates. Far less work has been conducted on "vital effects" in freshwater biogenic carbonates.

More work is needed to examine the relation between the $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ value of ambient waters and their biogenic carbonates. These efforts require relatively long term

monitoring of waters and related carbonates (a minimum of one year). In addition to monitoring the $\delta^{13}\text{C}_{\text{DIC}}$, $\delta^{18}\text{O}_{\text{water}}$, and temperature, measurements of pH, $[\text{HCO}_3^-]$, overall stream/lake productivity, the $\delta^{13}\text{C}$ values of potential food sources are needed to examine the seasonal variation in the $\delta^{13}\text{C}_{\text{DIC}}$ and the potential physico-chemical and biological causes of 'vital effects' (e.g., Dettman et al., 1999). In addition to environmental monitoring, detailed examination of the mechanism of calcification and physiological variation during the life history of individual organisms is needed.

Once such data are collected, empirical fractionation factors can be established for geologically significant species of plants and animals. A concerted effort by funding agencies is needed to establish these baseline data for modern organisms. Until these data are in hand, the utility of stable isotope data from archaeological and geological specimens will be in question.

Micro-Sampling Techniques

The development of micro-sampling or micro-milling techniques (the work of K.C. Lohmann and associates) to extract small amounts of powdered carbonate from ancient rocks, paleontological specimens, modern shells or otoliths, etc., together with the improved sensitivity of isotope ratio mass spectrometers (IRMS) has created a means of collecting very high temporal resolution data from such materials (Dettman and Lohmann, 1995; Wurster et al., 1999; Frappier et al., 2002). These automated micro-sampling devices are capable of routinely milling 15 to 20 μm -wide paths from biogenic carbonates – permitting sub-monthly sampling resolution in most specimens (Figure 1). These devices employ low eccentricity dental hand pieces equipped with precision drill bits, precision X-Y-Z stages and actuators, microscopes equipped with digital imaging devices, and custom software and motion controllers. Currently, these devices can be purchased commercially from two manufacturers.

Micro-sampling of biogenic carbonates with well-defined growth increments (mollusk shells, otoliths) is critical in deciphering ontogenetic variation in these materials (Figure 2). The importance of collecting sub-monthly resolution records from biogenic carbonates is the understanding of ontogenetic variations (associated with physiological changes such as sexual maturation and overall metabolic activity) and seasonal isotopic variation (induced by temperature and ambient conditions such as photosynthesis, respiration, and water column stratification). By collecting data at approximately bi-weekly intervals, one can examine short-term variation that would be overlooked by bulk analyses or lower-resolution sampling. Weekly to monthly sampling resolution is preferred as this is the temporal scale at which weather events occur (storms and surface water changes, cold front migrations, etc.) and to which the $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values of biogenic carbonates react.

Where shell growth rates are sufficiently rapid, high-resolution micro-sampling of biogenic carbonates is not needed. In such cases, more routine, manual sampling can be conducted to collect the appropriate temporal resolution for the project. The non-linear growth of unionid shells, both during an annual cycle (rapid extension rates in the Summer and slow growth rates in the Winter) and through

(a)

Figure 1 (a) Schematic diagram of an automated micro-sampler using a video camera for image capture (From Patterson and Smith, 2001, after Wurster et al., 1999). (b) Photograph of the Carpenter Microsystems CM-2 Micro-sampling System at the University of North Carolina. This system is equipped with a precision X-Y-Z stage with linear actuators permitting two inches of travel, a horizontally mounted precision handpiece, 15:1 stereoscopic zoom microscope equipped with both transmitted light and an epifluorescence illumination systems and a 12 mega-pixel digital camera. These systems allow for real time/on-screen digitization of sampling paths.

Figure 2 Close up schematic illustration of how individual micro-samples are milled from biogenic carbonate specimens using a rotating, faceted tungsten carbide drill bit. A first pass coarsely mills a trough parallel to the sample paths that allows the bit to shave small increments off one wall of the trough. These subsequent high-resolution paths are approximately 15 to 20 μm wide. Sample powders are manually removed from the specimen using a surgical scalpel. (From Patterson and Smith, 2002, after Wurster et al., 1999).

ontogeny (diminished growth rates with age) requires adjustments in sampling strategies.

Mid-latitude unionids from the Northern Hemisphere are thought to greatly reduce or cease carbonate precipitation below $\sim 12^\circ\text{C}$ (e.g., Howard, 1921 (*Lampsilis luteola*); Negus, 1966 (*Anodonta anatine*); Dettman et al., 1999). Both *Dreissena* sp. (Neumann et al., 1993) and *Corbicula* sp. (Joy, 1985) display little growth below 10°C . Interestingly, *Lampsilis radiata siliquoidea* from the Mackenzie River, NWT, Canada precipitates carbonate in water temperatures below 12°C (Carpenter et al., in prep.). The same species from more southerly latitudes in the United States (southeastern Michigan; e.g., Dettman et al., 1999) does slow shell production at this temperature. The occurrence of non-winter growth bands (pseudoannual bands) in unionids (slowing of shell carbonate production) seems to correspond to abrupt changes in ambient conditions (decreases in water temperature and O_2 levels; Carpenter unpublished data). Clearly, cessation of shell growth is not fully understood and requires examination of genera or species that are geographically widespread.

Cessation of shell growth in unionids results in a lack of data corresponding to the late Fall through early Spring in mid-latitudes. This lack of growth diminishes the ability to examine annual temperature minima, the $\delta^{18}\text{O}$ value of winter precipitation, and the oxidation of organic matter in lakes and streams. However, a uniform, Winter “shut-down” temperature allows calculation of ambient water $\delta^{18}\text{O}$ values by fixing temperature (assuming a known fractionation factor; e.g., Dettman et al., 1999). Given variation in shell growth rates, it's important to sample materials in a way that maximizes sampling efficiency with increased resolution during the Fall through Spring and perhaps a decreased resolution in the summer when shells are growing rapidly. This temporal “accordion effect” and the occurrence of Winter “shut downs” require special sampling strategies and data interpretations (see shell structure of pseudoannual and annual bands of Tevesz and Carter, 1980).

Many researchers have chosen to mill samples from the interior of unionid shells to avoid potential diagenetic alteration of the thin, outer prismatic layer of the shell. Although one should always assess diagenetic alteration, Quaternary age materials often do not exhibit extensive diagenetic alteration. In such cases, the outer surface of shells can be micro-sampled. One must use care to avoid drilling too deeply into the shell surface as these samples may sample carbonate that is older than that expressed at the shell surface. Dettman et al. (1999) found no difference in the $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values of the prismatic and nacreous layers of a modern *Lampsilis radiata siliquoidea* shell (Figure 3).

Unionid Bivalves and Freshwater Mollusks

Seasonal variation of $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values in freshwater mollusk shells from temperate settings produces sigmoidal or sinusoidal ontogenetic trends. In theory, the carbon and oxygen isotope ratios of shell carbonate will be negatively correlated with lower $\delta^{18}\text{O}$ value and higher $\delta^{13}\text{C}$ values occurring during the summer months when temperatures and primary productivity are highest (Figure 4). During the winter months (characterized by low temperatures and minimal productivity), $\delta^{18}\text{O}$

values reach their maximum and $\delta^{13}\text{C}$ values reach their minimum. The $\delta^{18}\text{O}_{\text{water}}$, temperature, and the $\delta^{13}\text{C}$ value of DIC (dissolved inorganic carbon or $\sum\text{CO}_2$) should play important roles in determining shell isotope ratios. There are several complicating factors that modify these theoretical parameters (e.g., specialized food sources, carbon cycling lag times, variable effects of chemical change on food-web dynamics, and the buffering capacity of the ambient water mass (the mass of carbon and oxygen upon which physico-chemical processes work)).

Lampsilis sp. – Huron River, Michigan

Dettman et al.'s (1999) examination of unionids from southeastern Michigan streams provided an introduction to how high-resolution data can be extracted and interpreted. Their data from *Lampsilis* (Huron River) are worthy of mention (Figure 3). There is a strong correlation between the $\delta^{18}\text{O}$ values collected from *L. o. ventricosa* and *L. r. siliquoidea*. Shell $\delta^{18}\text{O}$ values also are in isotopic equilibrium with ambient river

Figure 3 Shell $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values of two unionids from the Huron River, SE Michigan (*Lampsilis ovata ventricosa* and *Lampsilis radiata siliquoidea*). Shell thickness is measured perpendicular to nacreous plates, beginning at an arbitrary point before the 1990–1991 hibernation mark. The isotope records are aligned at $\delta^{18}\text{O}$ maxima. *L. o. ventricosa* data have been stretched by 45% to compensate for its slower growth. Lines connecting points are separated at visible “hibernation” or “shut down” features. Open circles are prismatic layer measurements of *L. o. ventricosa*. From Dettman et al. (1999).

water (Eqn. 5, Figures 3 and 5). The timing of variation in shell $\delta^{13}\text{C}$ values also correlates, yet maximum and minimum $\delta^{13}\text{C}$ values vary significantly between co-occurring species (Figure 3). Similarities between prismatic and nacreous layer isotope ratios confirm the utility of sampling the outer prismatic layer.

One can conclude that both species of *Lampsilis* are responding to similar environmental changes. The seasonal variation in $\delta^{13}\text{C}$ values is difficult to interpret in terms of measured variation in river temperature and $\delta^{13}\text{C}_{\text{DIC}}$ values and the relative timing of $\delta^{13}\text{C}$ value variation in the shells. It appears that there is a significant lag between stream productivity increases (marked by an increase in river $\delta^{13}\text{C}_{\text{DIC}}$ values) and shell $\delta^{13}\text{C}$ values.

Ricken et al. (2003) have found similar isotopic equilibrium precipitation in *Anodonta* and *Unio* from the Rhine River. This study examines the relation between isotopically distinct discharge from alpine and non-alpine catchments, using well documented surface water data. Their *Anodonta* specimens exhibit large decreases in $\delta^{13}\text{C}$ values during winter months (corresponding with high $\delta^{18}\text{O}$ values). Again, these values do not appear to be in isotopic equilibrium with ambient water DIC.

Pyganodon lacustris - Glovers Pond, New Jersey

The lacustrine unionid bivalve, *Pyganodon lacustris* occurs in *Chara*-rich sediment within the shallow water, carbonate bank (~1 m water depth) of Glovers Pond, NJ (Figures 6 and 7). Glovers Pond is a temperate, dimictic lake, in northwestern New Jersey and is spring-fed (through Ordovician dolomite). Today,

Glovers Pond is thermally and chemically stratified with a maximum depth of 9.5 meters and occupies a glacially modified and dammed fault valley currently being infilled concentrically by four types of sediment (peat, marl, calcareous-organic-rich silt, and gyttja, Erickson, 1968). The hypolimnion is undersaturated with respect to CaCO_3 which presently prohibits deposition of calcium carbonate in the deepest portions of the lake (Erickson, 1968). CaCO_3 (calcite) is deposited on a shallow shelf both on the surfaces of *Potamogeton* sp. and to a greater extent by blanketing growths of the green alga *Chara* sp. Marl and peat deposits form a platform that is prograding into the gyttja lithotope in the center of the lake basin (Figure 7).

Shell $\delta^{18}\text{O}$ values of *Pyganodon lacustris* record predicted seasonal changes in oxygen isotope ratios associated with variation in ambient temperature, rainfall, and evaporation. Shell $\delta^{13}\text{C}$ values record seasonal changes in lake productivity and stratification/overturn events (Figure 6). Warming of lake waters in the Spring yields a marked decrease in shell $\delta^{18}\text{O}$ values and the concomitant increase in productivity causes an increase in shell $\delta^{13}\text{C}$ values. Fall overturns (Oct.–Nov.) mix the cold, ^{13}C -depleted deep water (where organic matter is oxidized) with shallow waters. This produces a marked increase in shell $\delta^{18}\text{O}$ values and can produce as much as a 5‰ decrease in shell $\delta^{13}\text{C}$ values. Following this overturn, shell $\delta^{13}\text{C}$ values rise briefly (due to continued productivity in the lake) and then decrease abruptly (~7‰) as low temperatures diminish productivity in the lake and organic matter is oxidized (returning ^{13}C -depleted carbon from plant material back to lake waters). As stated previously, winter “shut downs” represent an unconformity in the shell isotope record when water

Figure 4 Idealized plot of unionid bivalve shell $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values and water temperature. Sinusoidal trends represent both $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values (scales for each at right). Winters (cold temperatures) are characterized by relatively high $\delta^{18}\text{O}$ values and low $\delta^{13}\text{C}$ values (due to oxidation or respiration (R) of plant material). Summers (warm temperatures) are characterized by relatively low $\delta^{18}\text{O}$ values and high $\delta^{13}\text{C}$ values (due to the removal of ^{12}C by photosynthesis (P) leaving DIC enriched in ^{13}C). Natural data will likely have seasonal changes in $\delta^{13}\text{C}$ values lagging behind $\delta^{18}\text{O}$ values. The 12 °C line represents the temperature at which shell carbonate may stop being precipitated. As a result, all data below this line may be missing in the unionid shell record. The resulting sinusoidal trends will likely have diminished seasonal amplitude and significant missing time associated with annual winter growth bands.

Figure 5 (a) Water temperatures and $\delta^{18}\text{O}$ values for the Huron River from October, 1990 to June, 1992. Filled triangles are temperatures that have associated water $\delta^{18}\text{O}$ measurements. (b) The $\delta^{13}\text{C}$ values of DIC from the Huron River and Fleming Creek, Michigan. These values correspond with shell data in Figure 3. From Dettman et al. (1999).

temperatures fall below $\sim 12^{\circ}\text{C}$. Spring overturns (Feb.–March) cannot be separated from the annual $\delta^{13}\text{C}$ minimum established by the cessation of productivity during the winter and the missing shell record. Return of lake productivity in the spring and summer produces a gradual increase in $\delta^{13}\text{C}$ values (by $\sim 6\text{‰}$) until this trend is modified by the next fall overturn.

Although these data suggest that lacustrine bivalves can provide a detailed seasonal record of temperature, stratification, and productivity in small lake basins, the $\delta^{13}\text{C}$ values of *Pyganodon lacustris* are lower than predicted equilibrium $\delta^{13}\text{C}$ values for shell aragonite. Grovers Pond $\delta^{13}\text{C}_{\text{DIC}}$ values are $\sim -6\text{‰}$ (Quevedo, 2003). Therefore, equilibrium $\delta^{13}\text{C}$ values of shell aragonite should be $\sim -3.3\text{‰}$. This finding, like those of other studies of unionids, is disappointing (e.g., Dettman et al., 1999). However, unlike other studies, data from *Pyganodon lacustris* indicate that it is responding directly to processes at work in this lake. Its growth within the *Chara* mat ringing the lake margin may provide a food source that quickly responds to changes in photosynthesis and respiration in the lake.

The work of Nichols and Garling (2000) and Christian et al. (2004) suggests that the food source of unionids is fine particulate organic matter that has a bacterial origin (not algal) and whose $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values vary with season (summer FPOM has lower $\delta^{13}\text{C}$ values than fall FPOM). Further examination of unionid food sources and growth environments is critical in understanding the complicated record of shell $\delta^{13}\text{C}$ values. Among the carbon fluxes in lakes and rivers are: carbonate precipitation, formation and oxidation of organic matter (algae, bacteria, mosses, terrestrial plant material, etc.), methane generation (in lacustrine peats), and bicarbonate-rich ground water.

Corbicula fluminea - Indonesia

Corbicula fluminea and *Dreissena polymorpha* are two invasive species that recently have grown in number in the St. Lawrence Seaway, the Great Lakes, and the Mississippi River due to transport by ships that carry these species in ballast water (see Drake

Figure 6 Plot of shell $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values from *Pyganodon lacustris* collected from Glovers Pond, New Jersey. Shell height is 43 mm. Data are plotted relative to sequential sample number to avoid compression of data. Samples were collected from the exterior of the shell (note white sampling swath) using manual micro-sampling techniques (from Carpenter and Erickson, in preparation). Winters represent a missing time/isotopic record.

and Bossenbroek, 2004; Holeck et al., 2004). As a result, these rather adaptive species have been studied extensively. Isotopic examination of their shells also has been conducted (Wurster and Patterson, 2001; Carpenter et al., 2005; Figures 8 and 9).

Corbicula sp. occurs naturally in streams and rivers in southeast Asia. A modern *Corbicula* sp. shell collected alive from a small stream in central Java has $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values that reflect a monsoonal moisture pattern (rainy and dry seasons; Figure 8(a)). The source of waters that feed these streams is rainfall on nearby volcanic peaks (~3000 meters high). Shell $\delta^{13}\text{C}$ values range from -14.9 to -12.3‰ and reflect a riparian vegetation of C3 plants (trees and shrubs).

The Upper Sangiran Formation in Central Java, Indonesia (~1.66 to 1.5 Ma) contains abundant *Corbicula* sp. shells in a paludal to lacustrine setting. This locality is of importance as it has yielded skeletal remains of *Homo erectus*. The first occurrence of *H. erectus* in the Upper Sangiran coincides with wet conditions and soil organic matter and fossil grasses that have high $\delta^{13}\text{C}$ values (~ -12‰ ; C4 Grasses). Grasses of this sort occur in poorly drained, wet conditions in southeast Asia (e.g., Johnston, 1996).

Corbicula sp. from this portion of the Upper Sangiran has $\delta^{13}\text{C}$ values that range from -7 to -1.8‰ (Figure 8(b)). Carbonate soil nodules from this unit have similarly high $\delta^{13}\text{C}$ values. Both soil and molluscan carbonates have $\delta^{13}\text{C}$ values that are ~10 to 11‰ higher than associated plant organic matter. This offset is consistent with the carbon isotope fractionation between CO_2 and carbonate (Emrich et al., 1970). Shell $\delta^{13}\text{C}$ values from modern *Corbicula* from this region are ~10‰ higher than their Pleistocene counterparts (Figure 8).

This suggests that the oxidation of plant material in soils and near streams is controlling the $\delta^{13}\text{C}$ value of shell carbonate (presumably via the $\delta^{13}\text{C}_{\text{DIC}}$). Given the tropical setting, cycling of carbon in these systems is likely very rapid, thus efficiently delivering CO_2 from organic matter decomposition to surface waters. This suggests that fossil mollusks from tropical regions may accurately record local vegetation.

In addition, the $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values of the Pleistocene *Corbicula* display no similarities with the modern monsoonal moisture pattern, but instead exhibit a sinusoidal trend reminiscent of temperate bivalves. In addition, Pleistocene $\delta^{18}\text{O}$ values are significantly higher than analogous modern data (Figure 8) suggesting either greater seasonal temperature variation and/or a markedly different source of precipitation that feeds local surface waters. Modern conditions are controlled by monsoonal rainfall with pronounced dry and rainy seasons. The dry season (May–Oct.) occurs when the ITCZ shifts to the north and dry air masses off Australia dominate. The rainy season (Nov. to April) occurs when the ITCZ shifts southward and humid air masses off SE Asia dominate. Paleosol and isotope data from the *Corbicula* in Figure 8(b) suggest that wet conditions persisted throughout the year without a dry season – perhaps during a glacial event.

Dreissena polymorpha - Keuka Lake, New York

Wurster and Patterson (2001) have conducted high-resolution sampling of the Zebra Mussel (*Dreissena polymorpha*) from Keuka Lake, New York (Figure 9). Shell $\delta^{18}\text{O}$ values closely match the equilibrium aragonite $\delta^{18}\text{O}$ values predicted by using measured water $\delta^{18}\text{O}$ values, the fractionation factor of Dettman et al. (1999) (Equation 5) and both water and air temperatures. Micro-sampling yielded 277 carbonate samples over 14 mm of shell growth (206 were analyzed). While one might debate the utility of sampling at this density, this work indicates that sampling methods can begin to address short-term events (i.e., storms, floods) in molluscan shell records.

Calcareous Algae and Aquatic Plants

Perhaps the most important producer of biogenic carbonate formed in freshwater is calcareous green algae. The family *Characea* (often referred to as Charophytes and *Chara*) is composed of macrophytic green algae that grow in oligotrophic ponds and lakes with relatively high bicarbonate contents. Most species of *Chara* sp. occur in the upper few meters of the water column and under elevated pH and $[\text{Ca}^{2+}]$ conditions, calcify heavily.

Chara, together with carbonate precipitation on aquatic plants such as *Potamogeton* are, to a large extent, responsible for the relatively rapid accumulation of carbonate sediments in marl lakes (Figure 7). This type of lacustrine calcification occurs predominantly during the late Spring to early Fall in temperate latitudes (due to elevated temperatures, photosynthesis, pH, and $[\text{HCO}_3^-]$; McConnaughey et al., 1994). Therefore, carbonates analyzed from lake sediment cores (marl lakes) must exhibit a strong bias toward Summer-time precipitation (e.g., Jones et al., 1996). This requires an explanation of stable isotope ratios that is consistent with physico-chemical conditions within the higher range of seasonal temperature variation (from ~20 to 35 °C for temperate settings). Another

Figure 7 (a) Location and bathymetric map of Glovers Pond, New Jersey. (b) Aerial photograph of the Glovers Pond Basin with *Chara* shelf and bog areas visible. (c) Photograph of the margin of Glovers Pond with the well developed *Chara* shelf and actively calcifying *Potamogeton* growing on the shelf slope. (d) Plots of $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values of modern *Chara* and *Potamogeton* carbonate. $\delta^{13}\text{C}_{\text{DIC}}$ is -6.5‰ and $\delta^{18}\text{O}_{\text{water}}$ is -4.8‰ (SMOW) following overturns. Precipitation of these carbonates under summer temperatures finds that these are precipitated in isotopic equilibrium with ambient waters.

factor in the interpretation of the $\delta^{18}\text{O}$ values of *Chara* calcite is its Mg content (e.g., Tarutani et al., 1969; Anadón et al., 2002).

Interpretation of $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values collected from cores of lacustrine carbonate sediment requires an understanding of the calcification method and the degree to which it is precipitated in equilibrium with ambient waters. There is some debate

over the degree to which Charaphyte carbonate is precipitated in isotopic equilibrium with ambient water (Huon and Mojon, 1993; Jones et al., 1996; Coletta et al., 2001). Both *Chara* sp. and *Potamogeton* sp. from Glovers Pond, New Jersey precipitate carbonate in carbon and oxygen isotopic equilibrium with ambient lake waters (Carpenter and Erickson, in prep.).

Figure 8 (a) Seasonal variation in $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values in a modern *Corbicula* sp. shell from Central Java. This plot depicts the differences between rainy and dry seasons. (b) Seasonal variation in $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values of a Pleistocene *Corbicula* sp. (Sangiran Fm) – note the higher $\delta^{13}\text{C}$ values and the presence of a sinusoidal trend – suggesting a lack of a monsoonal moisture pattern.

McConnaughey and Falk (1991) and McConnaughey (1991) describe possible calcification methods in *Chara* sp. where calcification occurs along alkaline bands on the exterior of the plant. Their data indicate a 1:1 ratio of calcification to photosynthesis. The extracellular precipitation of calcite by *Chara* as described by McConnaughey (1991) argues for minimal control of the calcification process by the plant and a greater likelihood of equilibrium precipitation (e.g., *Acetabularia* sp., Lee and Carpenter, 2001). If CO_2 hydroxylation plays a significant role in *Chara* calcification then one would anticipate a linear relation between $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values of its carbonate (McConnaughey, 1989a, b). In contrast, $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values collected from modern *Chara* exhibit minimal covariation in these values (Jones et al., 1996; Carpenter and Erickson, in prep.). Positive, linear covariation of $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values collected from carbonate-rich sediment cores (composed of predominantly Charophytes) from temperate, marl lakes (Drummond et al., 1995; Jones et al., 1996) is inconsistent with data from modern *Chara*. This linear covariation has been ascribed to a variety of lake physico-chemical

processes (stratification, CO_2 degassing, temperature variation, evaporation, seasonal changes in precipitation, etc.; Drummond et al., 1995; Jones et al., 1996). The time scales on which these data are formed (months for modern *Chara* and 10 to 100 years for sediment samples) likely account for some of this difference. As lake basins evolve over thousands of years, climate, reservoir size, vegetation, and various other parameters change. It is likely that this variation will impact the $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values of carbonate sediments. Clearly, more detailed examination of these processes is warranted.

Fish Otoliths

Otoliths (carbonate ear stones) of freshwater fish can be used to examine multi-year seasonal variation in $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values. The well-defined sclerochronology of sagittal otoliths (sagittae) provides a record that can be exploited using micro-sampling techniques (Figure 10). Typically aragonite, sagittae can be found in Quaternary age midden sites where fish were caught, eaten, and discarded (e.g., Wurster and Patterson, 2003). Preservation of otoliths is typically good in Quaternary deposits where materials have not been exposed to ground waters for prolonged periods of time. Stable isotope data have been collected from aragonite otoliths from Mesozoic age deposits (e.g., Patterson, 1999; Carpenter et al., 2003).

Two studies of the stable isotope ratios of freshwater fish otoliths are worthy of note. The first is an analysis of fossil freshwater drum (*Aplodinotus grunniens*) otoliths from an archaeological site in northeastern Tennessee (Figure 11; Wurster and Patterson, 2003). They examine intra-otolith variation in $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values from specimens that span the last 5500 years. This study contrasts data from high- and low-resolution sampling (Figure 11). This comparison points out how high-resolution sampling provides significantly more information about fish life histories (Figure 11(a)–(h)). Wurster and Patterson (2003) use the $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values of otoliths from different periods in the Holocene to estimate changes in bioenergetics induced by climate (a combination of temperature, metabolic activity, and other factors).

Wurster et al. (2005) examine intra-otolith variation of $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ value in chinook salmon (*Oncorhynchus tshawytscha*) from Lake Ontario (Figure 12). They study thermal histories (otolith $\delta^{18}\text{O}$ thermometry), stress, and metabolism (otolith $\delta^{13}\text{C}$ values) in this migratory fish. During the summer these fish inhabit epilimnetic waters with temperatures of ~ 19 – 20°C (Figure 12). Chinook would approach but rarely exceed their reported upper incipient lethal limit of approximately 22°C , which suggests that these fish were seeking water with temperatures as high as was tolerable while otolith growth occurred. These results contrast with expected midsummer temperatures for this typically cold-water fish. Bioenergetic simulations find that these salmon undergo significant stress at these temperatures. Increased catabolism and decreased gross conversion efficiency relative to nominal simulations where chinook salmon are modeled nearer their preferred temperature, confirms previous inferences that the chinook salmon population may be near the limits of sustainability (Wurster et al., 2005).

Figure 9 Example of high-resolution microsampling from freshwater bivalve *Dreissena polymorpha* from Keuka Lake, central New York (from Wurster and Patterson, 2001b). Digital image of *D. polymorpha* and illustration of a portion of the morphology of *D. polymorpha* determined using digital path coordinates; Comparison between predicted shell $\delta^{18}\text{O}$ values and measured shell $\delta^{18}\text{O}$ values for *D. polymorpha*. In order to satisfactorily compare the data and account for seasonal changes in the deposition of carbonate, different growth scales were used. A different growth scale was used from the umbo to the minimum shell $\delta^{18}\text{O}$ value and from the minimum shell $\delta^{18}\text{O}$ value to the last sample. In order to show a more detailed comparison, predicted shell $\delta^{18}\text{O}$ values determined using air temperatures from Rochester, New York and the fractionation factor of Dettman et al. (1999) (Eqn [5]) are also shown. Note that the scale was not changed for the date axis. However, Nov. through Mar. are omitted because predicted shell $\delta^{18}\text{O}$ values could not be determined for these months. Modified from Wurster and Patterson (2001b).

Figure 10 Schematic representation of a sagittal otolith depicting idealized growth bands (timelines). Microsampling paths follow these bands to extract intraotolith variation in $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values. Modified from Pannella (1980).

Discontinuous Records of Climate Change

The occurrence of freshwater biogenic carbonates during the Quaternary is quite variable. The most continuous carbonate records are of *Chara* sp. in lacustrine settings (i.e., lake sediment cores). Where rivers transport mollusks into lake basins, there is a potential to preserve more continuous records of mollusk shells. However, riverine deposits are by nature, discontinuous due to a variety of geological processes (e.g., meandering and channel migration, base level change and erosion, etc.). *In situ* riverine deposits containing mollusks and fish otoliths typically permit brief, episodic glimpses of seasonality and climate during periods of rapid deposition (e.g., flood events). Somewhat more continuous records of mollusk shells can be found in midden deposits. Where such deposits occur on flood plains, their continuous nature relies on the depositional and/or erosional qualities of the river and the extent to which humans or other organisms occupy a given site. Careful attention must be paid to the stratigraphic position, dating techniques used, position of paleosols, and bioturbation of midden deposits. In deposits where fire was used, researchers must use caution when analyzing charred biogenic carbonates.

Collection of long-term, continuous climate records from Quaternary age freshwater mussels and fish otoliths is not likely. Instead, isotopic records can be collected from relatively short intervals of time (typically a few thousand years) dictated by climatic conditions that are conducive to midden production. On a brighter note, well preserved specimens can yield a great deal of information regarding changes in seasonal temperature and water composition. Likewise, season of collection can be obtained in archaeological materials – a useful tool in understanding the timing of human habitation. For long-term climate interpretation, the best-case scenario is one in which well preserved materials occur episodically throughout a deposit where co-occurring dateable materials can provide precise limits on the timing of carbonate deposition (in particular, climatically important time intervals during the late Pleistocene and Holocene).

Figure 11 Otolith $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values of the freshwater drum *Aplodinotus grunniens* from northeastern Tennessee (Wurster and Patterson, 2003). (a) Intraotolith variation in high-resolution $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values of micromilled sagittae from time periods 0.3–2.9 ka. Samples were taken only from the first 8 yr of the sagittae or less. Each subplot represents an individual otolith. Each high-resolution sample represents an individual carbonate microsample. Low-resolution samples that approximate the average values of microsamples are plotted for comparison. Represented time periods are 0.3–1.0, 1.2, 1.4, 1.6, 1.7, 1.8, 2.7, and 2.9 ka. Specimens from A and B were destroyed before low-resolution sampling could be performed. (b) Intra-otolith variation in high-resolution $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values of micro-sampled sagittae from time periods 1.0 Ka, 2.3 Ka, 3.5 Ka, and 5.5 Ka. Each subplot represents an individual otolith. Each high-resolution sample represents an individual carbonate aliquot removed by micro-sampling. Low-resolution samples that approximate the average values of micro-sampled aliquots are plotted for comparison. Note different age axes on subplots. Subplots on the left side include samples only from the first eight years of the sagittae or less, whereas subplots on the right include samples from beyond the first eight years. The specimen from C was destroyed before low-resolution sampling could be performed. From Wurster and Patterson (2003).

Figure 12 Intraotolith $\delta^{18}\text{O}$ values and calculated temperatures (●) and $\delta^{13}\text{C}$ values (◊) relative to VPDB for the archived group of chinook salmon (*Oncorhynchus tshawytscha*) in Lake Ontario. Archived specimens were collected in 1991 from offshore waters of Lake Ontario. Each subplot represents one otolith from an individual fish. The $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values are plotted according to the number of the samples from the core of the otolith; note that $\delta^{18}\text{O}$ values are plotted with more negative values toward the top. The temperature scale (inset on y-axis) is calculated using a Lake Ontario $\delta^{18}\text{O}$ value of -6.8‰ (VSMOW) and Patterson et al.'s (1993) temperature–fractionation relationship for otolith aragonite of freshwater fish. Modified from Wurster CM, Patterson WP, Stewart DJ, Stewart TJ, and Bowlby JN (2005). Thermal histories, stress and metabolic rates of chinook salmon in Lake Ontario: Evidence from intra-otolith $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values and energetics modeling. *Canadian Journal of Fisheries and Aquatic Sciences* 62: 700–713.

Conclusions

Stable isotope data from freshwater biogenic carbonates have great potential for use in evaluating a variety of environmental conditions in the Quaternary record. Among these are: temperature, $\delta^{18}\text{O}$ value of surface waters, vegetation, timing of seasonal surface water productivity changes, and lake stratification. To enhance the utility of these measurements several advances need to be made: 1) Additional calibration of

geologically significant organisms, 2) Additional examination of the mechanisms responsible for biological fractionations or 'vital effects', and 3) Simultaneous analysis of carbonate minor element chemistry to develop an independent paleothermometer (e.g., Sr/Ca and Mg/Ca ratios). Elemental analyses come with their own caveats – such as calibration of modern materials, and understanding carbonate precipitation rates. Even with such advances, examination of multiple proxies is highly recommended (e.g., mollusks, otoliths, soil

organic matter, stalagmites, lacustrine sediments (carbonate, organic matter, pollen, mites, ostracodes, etc.).

Introduction

The Chironomidae constitute a family of true flies (Diptera) prominent as living larvae in the bottom communities of almost all freshwater habitats. They are abundantly preserved in Quaternary lake sediments, and are widely used for paleoenvironmental reconstruction. The biology and applications of Chironomidae in Quaternary science have been extensively reviewed by [Armitage et al. \(1995\)](#), [Frey \(1976, 1988\)](#), [Hofmann \(1986, 1988\)](#), [Porinchu and MacDonald \(2003\)](#), and [Walker \(1987, 1993, 1995, 2001\)](#). This entry provides a summary of these, and other important and relevant works.

Adult Chironomidae seldom bear a proboscis, and although they and their phantom midge cousins (family Chaoboridae) are mosquito-like, neither family shares the biting habit of mosquitoes (family Culicidae). Consequently, chironomids are commonly referred to as non-biting midges.

Three related families of aquatic midges do bite as adults and are also preserved as head capsules in lake sediments: Ceratopogonidae ('no-see-ums' or biting midges), Culicidae

(mosquitoes), and Simuliidae (black flies or buffalo gnats). Members of these families are vectors for many diseases of animals, including humans. Although Chaoboridae do not have a head capsule record, their mandibles are common fossils. Collectively, the preserved remains of Chironomidae, Chaoboridae, Culicidae, Ceratopogonidae, and Simuliidae are often referred to as fossil aquatic midges. The earliest known fossils of Chironomidae are of Triassic age.

The larvae, pupae and adults of all of these groups are important food items in the diets of fish. The adults (imagoes) are an important food for swallows and martins.

Biology

Chironomidae are amongst the most ubiquitous of insects, found on islands distributed throughout the world's oceans, and on all continents from the lowland tropics to the high arctic, Antarctic, and alpine. Chironomidae have a life cycle consisting of four stages: egg, larva, pupa, and imago.

Upon hatching, the first instar larva begins a period of growth, which eventually necessitates the shedding of the chitinous exoskeleton. Upon replacing the exoskeleton, the larva then continues growth in its second instar. Two further episodes of ecdysis (replacement of the exoskeleton) and growth follow, defining the third and fourth larval instars.

Although bearing a well developed, strongly sclerotized head capsule, the elongate soft-bodied larvae otherwise resemble maggots. As mature fourth instar larvae, they vary from 1 to 30 mm in length. Lacustrine chironomid larvae inhabit the uppermost sediments of both littoral and profundal (deepwater) environments, cling or burrow into aquatic plants, tunnel in moist wood, or live as parasites or commensal partners on other invertebrates. Similar habitats are occupied in streams, and chironomid taxa are known to inhabit littoral marine environments, water-logged soils, peats, and dung.

The first instar larva of lacustrine midges is generally planktonic, allowing for dispersal of larvae to suitable substrates. Larvae from habitats other than standing water, and the later instars of lacustrine midges, are largely sedentary and benthic (bottom dwelling). The first instar is typically brief, with each later instar usually of progressively longer duration. Although the first instar larvae may derive some nourishment from the egg yolk, they feed on a variety of materials including algae, organic detritus, aquatic plants, and other invertebrates. Some are predaceous, whereas most other chironomids combine algae and organic detritus to form their diet.

During the latter part of the fourth larval instar, the thoracic segments expand, achieving a pre-pupal condition. Following ecdysis, the chironomid enters the pupal stage in which morphology is re-organized to that of the imago (adult). Apart from the Tanypodinae, almost all pupae are sedentary. The pupal stage is brief, persisting for a few days at most. At maturity, the pupa moves to the water surface, allowing emergence of the winged adult.

Lasting for a few weeks only, the adult stage permits dispersal and reproduction. The duration of the midge life cycle varies greatly among taxa, and is also related to habitat. Long life cycles typify arctic taxa, occasionally extending to several years. In warmer climates, several generations are common in a single season.

Classification

Eleven subfamilies constitute the Chironomidae. One subfamily, the Telmatogetoninae, is almost completely restricted to marine environments. However, in Hawaii this family also inhabits fresh water. Three subfamilies are very rare, or known only from a small segment of the world. For example, the Chilenomyiinae, represented by a single species, is known only from southern Chile. The Buchonomyiinae includes three species native to Europe, Asia (Burma), and Central America (Costa Rica). The Usumbaromyiinae is a new subfamily recently described from Tanzania (Andersen and Sæther, 1994).

The subfamily Aphroteniinae, including four genera, is known only from South America, South Africa, and Australia. Such a distribution suggests that this primitive group originated before the Mesozoic disintegration of Gondwanaland. An extinct Aphroteniinae tribe, the Electroteniini, records this subfamily's former, more widespread Cretaceous distribution, extending into Siberia.

Three subfamilies, the Orthoclaadiinae, Tanypodinae, and Chironominae, are widely distributed and constitute the majority of taxa encountered in lake sediments. The remaining subfamilies, Podonominae, Diamesinae, and Prodiamesinae, are predominantly cold-stenothermous taxa inhabiting temperate and montane, to polar and alpine climatic regions.

Fossils and their Identification

Taphonomy

Given an appropriate sedimentary environment, remains of larvae, pupae, and adults (imagoes) may all be preserved. Imagoes are well preserved in Cretaceous amber, but in lake sediments their bodies are commonly disarticulated. Occasionally the hypopygium, a part of the male imago's genitalia, is preserved and allows species-level identifications. Thoracic horns of Tanypodinae pupae have rarely been found in lacustrine deposits, and the thin, delicate bodies of larvae and pupae are too fragile to normally preserve well. In contrast, Quaternary interglacial lake deposits typically contain 50 to 200 well-preserved larval head capsules per cubic centimeter. Thus, these well sclerotized head capsules are far more abundant in lakebeds than the remains of all other insects combined. They provide the basis for almost all Quaternary paleoenvironmental work involving the Chironomidae.

One head capsule is produced by each chironomid, during each larval instar. Thus, a chironomid surviving to the fourth larval instar will have produced four head capsules. A chironomid expiring prior to attaining its fourth instar will produce fewer head capsules. The head capsules subsequently preserved could include both those shed with exuviae during ecdysis, and the remains of dead larvae. However, there exist numerous reasons why the abundance of fossil midge remains might not reflect the abundance of the living larvae from which they were derived.

Quality of preservation may vary among taxa, among instars, and between head capsules derived from expired insects and those shed as exuviae. Bivoltine and multivoltine taxa produce more head capsules per season than univoltine taxa of the same abundance. Re-distribution of head capsules will influence the concentration and composition of fossil assemblages. Remains of stream Chironomidae are often deposited in lakes, and remains of littoral species may be transported offshore to deepwater sites. Erosion along lakes and streams facilitates the redeposition of semi-terrestrial species into lacustrine settings.

Iovino (1975) determined that first and second instars of *Chironomus attenuatus* usually dissolve the procuticle completely prior to ecdysis, leaving only a thin, non-chitinous, epicuticular exuviae. In contrast, third instar exuviae usually include chitin, and fourth instars of *Chironomus attenuatus* were chitinous almost without exception. Thus, exuviae of early instars are much less durable than both those of later instars and remains of expired larvae.

These experiments have only been conducted on *Chironomus attenuatus*. The results possibly apply to all chironomid species. This, in part, would explain the great under-representation of early instar head capsules in lake sediments. Early instar remains may also be lost through the use of coarse sieves during processing.

Tanypodinae head capsules are more delicate than those of other taxa, and may be poorly preserved. First instar head

Figure 1 Representative fossils of Chironomidae, illustrating the principal structures used in their identification: (a) *Procladius* (subfamily Tanypodinae), (b) *Sergentia* (tribe Chironomini, subfamily Chironominae), (c) Tribe Tanytarsini (subfamily Chironominae), (d) *Psectrocladius* cf. *calcaratus* (Subfamily Orthocladiinae). Abbreviations: a1, 1st antennal segment; lg, ligula; md, mandible; mt, mentum; vp, ventromental plate.

capsules of all chironomid taxa are normally uncommon to rare as fossils, but may dominate records preserved in the anoxic, deepwater regions of meromictic basins.

Fossil Morphology

Identification of Quaternary fossils relies principally on the morphology of the head capsule, although other larval body parts (e.g., antennae and various mouthparts) are useful when they are still attached to the head. The structure of the head capsule varies, but the greatest part of this variation may be illustrated with reference to fossils of the subfamilies Chironominae, Orthocladiinae, and Tanypodinae (Figure 1).

The head capsules of Tanypodinae (Figure 1(a)) are generally weakly pigmented and somewhat elongate. The retracted first segment of each antenna is often visible within fossil head capsules. The proportions (ratio of length to width) of the head capsule and first antennal segment can be important characters for fossil identification. A fork-shaped ligula is centrally located within the head capsule. The ligula may become separated from head capsules during burial or processing of fossil material. Variations in the shape, number, and color of ligula teeth also aid identification. The dorsomental teeth, lacking in the tribe Pentaneurini, are otherwise situated laterally adjacent to the ligula and will usually remain with the head capsule. In well preserved material, one or both mandibles may be retained. The arrangement of minute hairs (cephalic setae) on the fossil head capsule is also important for identification of larval fossils (Rieradevall and Brooks, 2001).

The principal features facilitating identification of fossil Chironominae (Figures 1(b) and (c)) and Orthocladiinae (Figure 1(d)) are the ventromental plates and the teeth of the mentum. The mentum is situated in an anterior median ventral position. The pair of ventromental plates are situated laterally,

adjacent to the mentum on either side. In the Chironominae, the ventromental plates are very large and usually conspicuously striated. Although fan-shaped in the tribe Chironomini (Figure 1(b)), laterally elongated, strap-shaped plates occur on members of the Tanytarsina (a subtribe of the tribe Tanytarsini) (Figure 1(c)), and in the tribe Pseudochironomini.

In the Orthocladiinae (Figure 1(d)), the ventromental plates are typically much less conspicuous, and never striated. In many Orthocladiinae, these plates are greatly reduced, vestigial structures. In all Chironominae and Orthocladiinae, the shape, number, and arrangement of the mental teeth and characteristics of the ventromental plates are critical diagnostic features. Most other structures are normally lost from the head capsule.

Although taxonomic keys for living larvae rarely permit identification of fossil larval head capsules, reference to associated illustrations and diagnoses for each genus usually permit classification. Fortunately, most of the characters employed by systematists are borne on the head capsule and consequently may be available for fossil work. Few keys have been designed specifically for fossil identifications.

Sample Preparation

Meticulous preparation, sorting, and identification of midge remains are requisites for analysis of past communities. Small lakes in forested watersheds usually contain sediments with a high organic content. In such lakes, 1 or 2 ml of wet sediment typically contains 50 to 200 head capsules, sufficient for analysis. Inorganic sediments, such as those frequently encountered in Late Glacial deposits, may yield much lower concentrations. However, head capsule concentrations vary greatly among sites.

Samples are usually deflocculated in 5 to 10% KOH prior to analysis. In calcareous sediments, an acid wash (10% HCl) may also be necessary. If excessive siliceous mineral matter is present, HF may be used to further concentrate and clean the head capsules. Following these chemical treatments, head capsules are generally separated from finer debris by means of sieving. Methodology varies, but a 100 µm or finer sieve will retain most head capsules and is recommended. Subsequently, the residue is back-washed from the sieve into a container and stored wet until the material is sorted. Unless sorted shortly after sieving, preservation in 99% ethanol is advisable. Sorting of wet residues is best accomplished in a Bogorov counting tray at 40 to 50X. As remains are located, each is transferred with forceps to coverslips, for mounting in an appropriate medium (e.g., Canada balsam, Euparal®, or Entellan®) and subsequent identification.

Ecology and Distribution

Early work on the ecology and distribution of Chironomidae was conducted by biological limnologists (e.g., August Thienemann, Lars Brundin, Ole Sæther) who sought to classify lakes principally with regard to biological productivity. They also emphasized the importance of Chironomidae as bio-indicators of water quality. The importance of water quality parameters, especially food quantity, food quality, and the oxygen concentration at the mud–water interface were considered of paramount importance in regulating the distributions of larval Chironomidae.

Large-bodied larvae, which contained hemoglobin (especially *Chironomus*), were noted as best adapted to the oxygen-deficient bottom waters typical of eutrophic lakes (nutrient-enriched lakes with high algal production). Hemoglobin facilitates the capture and storage of oxygen, whereas large body size allows the larvae to disrupt, and extend their bodies above, the most oxygen-deficient micro-layer at the mud–water interface. In contrast, small-bodied larvae, which lacked hemoglobin (several Tanytarsina and Orthocladiinae), were better adapted to low food availability in the well-oxygenated bottom waters of oligotrophic lakes (nutrient-poor lakes with low algal productivity). Because of these relationships among chironomids, water quality, and oxygen concentrations, extant chironomid communities are sampled extensively for environmental biomonitoring purposes. The Benthic Quality Index, for example, was developed as a means for environmental assessment in Nordic freshwater lakes (Wiederholm, 1980).

Detailed surveys of chironomid distributions in North America and Europe have revealed the importance of other environmental variables. Recent studies continue to recognize the importance of oxygen and biological productivity as controls on species distributions, but greater importance is commonly extended to climatic variables, especially summer air and water temperatures. The Chironomini and Tanypodinae are abundant and widely-distributed in temperate to tropical climates, but the subfamilies Orthocladiinae and Diamesinae, and some members of the subtribe Tanytarsina, are more abundant where colder, alpine and polar climates prevail. In addition to temperature and oxygen, salinity, pH, dissolved organic carbon, nutrient concentrations, and lake depth are

considered important variables defining the distributions of individual chironomid species.

Quaternary Paleoecology

Lake Ontogeny

Early chironomid paleoecological research was primarily directed to answering questions pertaining to lake ontogeny (i.e., those physical, chemical, and biological processes that influence how lakes intrinsically tend to develop through time). Einar Naumann (1919) speculated that lakes should gradually become less productive as a consequence of constant leaching of catchment soils. Many other limnologists, including Naumann's contemporary August Thienemann (1926), perceived eutrophication (a gradual increase in lake productivity) as the dominant, if not universal process. Whiteside (1983) traces this perception to early works published by Lindeman (1942) and Deevey (1955). Deevey emphasized that the gradual infilling of lakes, by reducing the volume of the hypolimnion (the cold-water region at the bottom of the lake) could generate an O₂-poor hypolimnion. Release of phosphorus, an important nutrient, from the sediments beneath the hypolimnion could then produce an increase in lake productivity. This process was dubbed morphometric eutrophication.

This appealing theory was broadly supported by early chironomid paleoecological studies, which suggested a shift from midge communities typical of well-oxygenated, nutrient-poor (oligotrophic) lakes, to those prevalent in the deep water of oxygen-deficient, nutrient-enriched (eutrophic) lakes. However, the theory was developed from a relatively small subset of the world's lakes (i.e., temperate lakes, formed during the relatively recent deglaciation of eastern North America and northwestern Europe), and was never tested more generally on lakes with different origins, or in other climatic regions.

These early investigators also failed to recognize or acknowledge the potential importance of climate in driving the observed changes in both midge fauna and lake productivity. Major changes in the midge faunas typically occurred at each site with the development of forests and rapid deglacial warming approximately 10,000 ¹⁴C yr BP.

Today, these changes in productivity and midge communities are more likely to be interpreted as a consequence of climatic change, not as an intrinsic tendency of lakes to become more productive over time. The importance of climate as a driving force in lake productivity and midge community change is especially evident in late-glacial records, where increases and decreases in the apparent productivity of lakes and changes in midge faunas, coincide with independent evidence of climatic changes. The apparent productivity of lakes abruptly decreases and oligotrophic midge communities return, with the onset of colder conditions.

Human Impact Studies

Although the natural productivity of lakes and their midge faunas may be regulated more by climate than initially recognized, human activities have also had major impacts. Given the long history of environmental biomonitoring using living Chironomidae, there has also been long interest in using the fossils in paleoenvironmental assessments of human impacts.

Some researchers have used mouthpart deformities as indicators of environmental stress (e.g., in the Rhine), but most results are derived from stratigraphic studies of midge community composition, as preserved in lake sediments.

Eutrophication

Increased nutrient loading, for example, from urban and agricultural land use may dramatically increase the productivity of some lakes, to the point where algal blooms foul shorelines and their decomposition produces anaerobic conditions within the hypolimnion. In addition to this increased organic production from nutrient enrichment, external inputs of sewage and other organic wastes compound the de-oxygenation problem.

Since chironomid communities respond dramatically to such trophic alterations, their remains provide a detailed record of eutrophication events. Most studies (e.g., at Esthwaite Water and Lough Neagh (UK), Lake Washington (US), Wood Lake, and Bay of Quinte, Lake Ontario (Canada), Lake Mälaren and Lake Vättern (Sweden), Lake Vanajavesi (Finland)) have relied on qualitative interpretation of midge stratigraphies for impact assessment. In recent years, researchers have instead attempted to develop quantitative reconstructions of productivity related variables.

Most researchers would argue that hypolimnetic oxygen concentrations have the most important and most direct impact on living larvae; thus a quantitative model that infers paleo-oxygen conditions, should ideally be developed. Oxygen conditions vary continuously throughout the year, and also at different depths in the water column, so it is difficult to characterize a lake's oxygen level with a single oxygen measurement. Furthermore, the duration of anoxic conditions and the build-up of toxic H_2S in anoxic hypolimnia, are probably equally important variables. The relationship between midge communities and oxygen concentrations is even more tenuous in shallow lakes (lacking a hypolimnion) and in near-shore (littoral) habitats, than in deep, thermally stratified hypolimnia.

As an alternative to reconstructing oxygen levels, researchers have developed models to infer phosphorus or chlorophyll concentrations. The connection between inorganic nutrients, such as phosphorus, and their impacts on chironomid larvae is indirect, but nutrient concentrations are more easily measured and more widely used to characterize lake productivity. These midge-productivity models are now being used in North America and Europe to better quantify human impacts on the environment. Brodersen and Quinlan (2006) review recent pertinent literature.

Acidification

During the 1980s, lake acidification and the long-range transport of air pollutants were amongst the most controversial and internationally important environmental issues. Much environmental research was devoted to tracing the paths of pollutants, and assessing their damage to ecosystems in both eastern North America and northern Europe. Little was known about the distributions of chironomids with respect to pH, alkalinity, or related environmental variables, but they were used as biomonitoring tools in several studies of lake acidification.

pH is a master variable in aquatic chemistry. Many other variables, for example, lake alkalinity, dissolved organic carbon, and metal concentrations, tend to co-vary with pH, thus it

is difficult to separate the direct effects of pH from the effects of these covariables. At low pH, metals (e.g., Fe, Al) are more soluble, and some (e.g., Al) are known to be toxic to aquatic organisms. However, many acidic lakes are also humic lakes, containing high concentrations of dissolved organic acids.

The organic acids are derived from the incomplete decomposition of terrestrially-derived organic matter, especially from adjacent bogs. These organic acids are natural products, which may contribute to the acidity of lakes, but may also slow the rate of decomposition and bind to nutrients (e.g., P) and metals (e.g., Al), reducing the impact of these pollutants on aquatic life.

Chironomidae are well represented even in strongly-acidic waters (pH 3.5 to 5.5). *Chironomus*, *Phaenopsectra*, *Psectrocladius*, and *Zalutschia* are reported at greater relative abundance at low pH. Favored taxa tend to be large-bodied, having smaller surface areas relative to volume. It may be easier for large larvae to maintain their internal pH balance. Those midges abundant in acidified lakes include taxa reported to be more common in fish diets. Thus acidification, by eliminating fish, could also favor these taxa. Furthermore, the increased buffering capacity afforded by hemoglobin may also favor hemoglobin-bearing larvae.

Although several paleolimnological studies have documented changes in midge populations that accompanied lake acidification, these insects have never been used to quantitatively reconstruct pH. Although technically feasible, the chironomid-pH relationships have never been properly quantified. Once the pH optima and tolerances of chironomid taxa are quantified, they should be useful bio-indicators of lake acidification processes. This is an obvious area to target in future research.

Climate Change

Paleotemperature

Although researchers had previously pondered the possible climatic significance of midge stratigraphies, it was not until the late 1980s and early 1990s that midge-climate relationships were explored in earnest. At first, the possibility of using chironomids for paleoclimatic inference was highly controversial, stimulating a lively debate in Quaternary Research, the Journal of Paleolimnology, and the Canadian Journal of Fisheries and Aquatic Sciences.

Key to resolving the issue was an international effort to map the distribution and abundance of chironomid taxa across long climatic gradients in both North America and Europe. Statistical analyses of these data repeatedly demonstrated that summer air and water temperatures were highly correlated with midge distributions.

Summer climate is now recognized as potentially the single most important variable regulating midge distributions. Fossil midges are also recognized as one of the most reliable indicators of past climatic change. Through the use of statistical inference procedures (e.g., weighted averaging, partial least squares, analog matching, and Bayesian methods) midge-climate models are routinely used in the quantitative reconstruction of late-glacial and Holocene paleotemperatures. Details of the midge-climate relationship, however, are still widely debated. At least in part, midges may be responding to climate indirectly via the influence of climate on lake productivity.

Surveys of midge distributions spanning the treeline commonly reveal distinct forest and tundra communities, with species turnover being most rapid in the vicinity of the treeline.

This observation suggests that treeline communities may be highly sensitive to climate change, and these sensitive sites are targeted by paleoecologists for paleotemperature reconstructions. Conversely, these transects suggest that the fauna within the forest region is more uniform, and insensitive, so such insensitive sites tend to be ignored by paleoecologists. This bias is also likely to impact on midge-derived paleotemperature reconstructions. From the perspective of a researcher wishing to accurately reconstruct paleotemperatures, treeline sites may be overly sensitive, revealing paleotemperature signals larger than the changes that actually occurred, whereas forested sites may pose the opposite dilemma. This issue has implications for accurately reconstructing: 1) the temporal magnitude of paleoclimatic changes, and 2) spatial temperature gradients, for example, as they existed at the margin of ice sheets (Levesque et al., 1997).

Brooks (2006), and Walker and Cwynar (2006) review recent progress in paleotemperature reconstruction using fossil midges.

Lake levels

Statistical analyses have revealed a number of other environmental variables potentially critical for understanding midge distributions. Lake depth, for example, is often just as important as temperature. Since lake levels have often been used as indicators of hydrological balance, lake depth inferences might provide another useful tool for paleoclimatologists. During warm, dry intervals lake levels may drop. During cool, wet intervals lake levels will rise.

Midge–depth relationships are easily modeled for use in lake level reconstructions. Despite this opportunity, midges are seldom used for lake level reconstructions. Model errors indicate that satisfactory reconstructions will only be possible where the amplitude of lake level changes has been very large. Since the surface discharge from lakes can change enormously with small changes in lake level, inferences obtained from open basin lakes are unlikely to provide useful information. The magnitude of lake level changes in closed basin lakes is potentially much larger. These lakes are common in semi-arid regions and potentially contain more useful paleohydrological records.

Paleosalinity

Although not extensively studied, chironomid communities are known to be salinity sensitive. This is never evident in freshwater regions, but saline lakes are common landscape features, for example, in Australia, east Africa, central Asia, and western North America. As in other aquatic organisms, the osmotic stress imposed by high salinities tends to dehydrate larval midges. Many species are intolerant, restricted entirely to fresh water, but a few (e.g., *Cricotopus ornatus* and *Tanytus nubifer*) thrive in highly saline lakes or in marine intertidal habitats.

Since hydrological balance (evaporation/precipitation) potentially regulates the salinity of these lakes, midges and other paleosalinity indicators (e.g., diatoms) may provide important paleoclimate proxy data from these sites. During warm, dry intervals salinity is expected to be high, and during cool, wet intervals salinity should be low. Midge paleosalinity reconstructions are now available for several sites in Africa and western North America. Recent evidence suggests that the paleohydrology of these lakes may be very complex. Paleosalinity reconstructions may be more difficult to interpret climatically than previously assumed.

In addition to their potential climatic significance, midge paleosalinity records may be useful for sea-level studies. Heinrichs and Walker (2006), and Verschuren and Eggemont (2006) have reviewed the potential of midge paleosalinity records for both paleohydrological and sea-level studies.

Glossary

Alpha-diversity: Refers to the diversity within a particular area or ecosystem, and is usually expressed by the number of species (i.e., species richness) in that ecosystem.

Anoxia: The absence of oxygen necessary for sustaining most life.

Autoecology: The ecology of an individual species in its natural environment, without consideration of its interactions with other species.

Benthos: Collectively, all organisms living on or in the bottom of a lake, stream or other water body.

Beta-diversity: A comparison of diversity between ecosystems or biomes, usually measured as the amount of species change between the ecosystems.

Calibration data set: A set of species collected from modern sites along with relevant environmental data, often related to one another using a series of quantitative inference models. Calibration data sets form the basis for quantitative paleoecological reconstruction when used in conjunction with fossil assemblages. Used to generate inference models. See inference model.

Canonical correspondence analysis (CCA): A constrained ordination technique based on correspondence analysis, but where the ordination axes are constrained to be linear combinations of the supplied environmental (predictor) variables.

Conductivity: Here a measure of the ability of water to conduct an electric current due to the presence of dissolved solids, normally expressed as microsiemens/cm ($\mu\text{S cm}^{-1}$) or micromhos/cm ($\mu\text{mhos cm}^{-1}$).

Correspondence analysis (CA): An ordination method that simultaneously ordines samples and variables (species), and maximizes the correlation between sample and variable scores. It is widely used in ecology because it assumes a unimodal response of species variables to underlying gradients.

Direct ordination: An ordination in which the important gradients are known and measured. See ordination.

Ecotone: The boundary or transition area between two or more habitats or communities.

Halobiont: Living or growing in a salty environment.

Holomictic: Used for lakes which have complete circulation of the water column.

Hypersaline: Having a total dissolved solid content (salinity) greater than about 40 ppt (parts per thousand) or $60\,000\ \mu\text{S cm}^{-1}$.

Hypolimnion: Cold-water region at the bottom of a thermally stratified lake.

Indicator species: A species whose presence is a marker for a specific habitat condition or environmental value.

Indirect ordination: An ordination in which gradients are unknown *a priori*, and are inferred from species composition data.

Inference model: A mathematical function that describes the relationship between biological species and environmental variables that allow the past values of an environmental variable to be inferred from the composition of a fossil assemblage.

Littoral zone: The zone in a lake or pond extending from the shore to the greatest depth at which rooted plants occur.

Maximum likelihood: A method of environmental reconstruction based on the idea that the relation between the abundance of a taxon and the environmental variable of interest can be modeled by an ecological response curve consisting of a systematic and a random (error) component. Together, the curves of all taxa determine what taxa composition is expected at a given conductivity value. This model of responses and their error structure is used to calculate the probability that a particular value would occur with a given assemblage. The value that gives the highest probability is the maximum likelihood estimate.

Meromictic: Used for lakes which do not undergo complete mixing of the water column at least once each year.

Mesosaline: Degree of salinity in brackish to marine waters; water having a total dissolved solid content (salinity) of 5.0–18.0 ppt or $8000\text{--}30\,000\ \mu\text{S cm}^{-1}$.

Modern analog technique: A method of environmental reconstruction based on matching fossil samples to modern surface-sediment assemblages of similar taxonomic composition.

Morphotype: In this context, group of fossil specimens which are considered to belong to the same species, group of species or a higher unit based on shared morphological characters alone.

Oligosaline: Having a total dissolved solid content salinity between 0.5–5 ppt.

Ordination: The collective term for multivariate techniques that arrange sites along axes on the basis of data on species composition; the usual objective of ordination is to help generate hypotheses about the relationship between the species composition at a site and the underlying environmental gradients.

Osmotic stress: Physiological stress caused when the salinity of an animal's environment changes drastically.

Oxycline: A horizontal boundary layer in the water column, at which dissolved oxygen content changes sharply with depth.

Polysaline: Water having a salinity of 18.0–30.0 ppt or $30\,000\text{--}45\,000\ \mu\text{S cm}^{-1}$.

Profundal: Pertaining to deep-water bottom habitats in lakes.
Proxy data: In this context, data obtained from natural environmental archives and used as surrogates (proxies) for the past condition of another variable, such as past temperature or precipitation, that cannot be measured directly.

Weighted-averaging: In environmental reconstruction, a numerical technique to derive inference models by estimating species optima from the calibration data set (i.e., regression), and then using these optima to estimate the past value of an environmental variable from a fossil assemblage (i.e., calibration). The fundamental assumption of the

technique is that the weighted average of a taxon represents the conditions for which this taxon is most abundant. The species optima and tolerances are estimated from the weighted averages and weighted standard deviations, respectively.

Weighted-averaging partial least squares: An extension of weighted-averaging and calibration where two or more components, that utilize the residual structure in the modern biological data, are used to improve the predictive power of the inference model.

Zoobenthos: Invertebrate animals that live in or on the bottom of a lake, stream or other water body.

Introduction

Building on the tradition to exploit chironomid larvae (Insecta: Diptera: Chironomidae) as biological indicators in contemporary water-quality monitoring of lakes and rivers (Rosenberg, 1993), paleolimnologists are making increasingly profitable use of their fossil remains preserved in lake sediments to reconstruct long-term environmental change affecting lakes and adjacent landscapes (Walker, 1995). In north-temperate Europe and North America, chironomid paleoecology (and particularly chironomid paleoclimatology) is now a mature research discipline (Walker, 2001), involving statistically robust inference models for quantitative reconstruction of past changes in temperature, salinity, lake trophic status, and oxygen regime. In tropical regions including Africa, the growth of chironomid paleoecology as a rigorous, quantitative research discipline has been decidedly slower. The principal reasons for this geographical imbalance are incomplete taxonomic knowledge of tropical Chironomidae (and in particular their larval stage), the scarcity of autecological information that would confer bio-indicator value to local taxa, and the logistic (sometimes also political) difficulties hampering the comprehensive ecological lake surveying needed to obtain this information. Although continuous high-resolution chironomid records spanning the entire postglacial period in Africa are thus far lacking, African chironomid paleoecology has made substantial progress over the past decade (Verschuren and Eggermont, 2006). In this article, we provide an overview of its present status, dealing successively with chironomid records of past environmental change, advances in methodology, and taxonomy.

Chironomid Records of Past Environmental Change in Africa

Fossil Chironomidae have so far contributed to eight paleoenvironmental reconstructions from tropical Africa (Eggermont et al., 2008b; Mees et al., 1991; Ryner et al., 2007; Ryves et al., 2011; Verschuren et al., 1996, 1999b, 2000a, 2002). Mees et al. (1991) reconstructed Holocene lake-level and salinity changes at Malha crater lake in Sudan (15° N 26° E), one of very few permanent waters in the eastern Sahara desert. The lithology and mineralogy of its sediment sequence indicated that six successive lake phases had occurred over the past 8300 ¹⁴C

years, separated by severe lowstands or complete desiccation. The timing of these hydrological changes is poorly constrained, due to lack of high-quality radiocarbon dating targets, but their pattern is consistent with the regional history of millennial-scale fluctuations in rainfall and drought (Hoelzmann et al., 2004). In the early- to mid-Holocene, the lake was deep and meromictic, with surface waters evolving from fresh (as indicated by the presence of *Dicoretendipes fusconotatus*, *Dicoretendipes sudanicus* and *Nilodorum brevibucca*) to mesosaline (indicated by presence of the salt-loving *Kiefferulus disparilis*). The authors interpreted this evolution as a reflection of decreasing rainfall and shrinking groundwater input, which both reduced new freshwater inflows and caused wind-driven mixing to bring increasing amounts of deep salty water to the surface. During the last ~4000 years, Malha Crater Lake was most often shallow and holomictic, and poly- to hypersaline. Chironomidae became locally extinct, and were replaced only by scattered occurrences of other salt-loving midges, such as the brine fly *Ephydra* (Ephydriidae), the biting midge cf. *Culicoides* (Ceratopogonidae), and an unidentified soldier fly larva (Stratiomyidae). Clearly, the late Holocene aquatic environment in Malha Crater approached the limit of what African aquatic invertebrate communities can tolerate.

Verschuren et al. (1996) used the relative abundance of (semi)terrestrial, lake, and stream chironomids extracted from a peat deposit at Kashiru, Burundi (2100 m a.s.l., 3° S 30° E) to describe the general late-Quaternary evolution (last ~40 000 years) of this cold aquatic habitat in the mountains northeast of Lake Tanganyika. Peat sequences are the traditional source of African pollen records, but this is the only study so far which exploited them for chironomid paleoecology. Chironomid genera that are widely distributed in lowland African lakes (*Chironomus*, *Cladotanytarsus*, *Dicoretendipes*, *Kiefferulus*, *Nilodorum*, *Polypedilum*, and *Procladius*) were absent or scarce in the fossil assemblages found at this site; consequently, the ecological literature on African lakes was of little use to their interpretation. Instead, the authors made inferences on past habitat conditions mostly by transferring Holarctic ecological typology (Merritt and Cummins, 1984), assuming that cold-adapted African representatives of Holarctic genera would have similar habitat preferences. Chironomid fossils were markedly concentrated in core sections consisting of decomposed or only slightly fibrous peat, which presumably had been deposited in peat hollows. Strongly fibrous peat (from hummocks)

and sandy horizons (indicating an episode when the local environment was too dynamic to allow peat accumulation) were typically devoid of fossils. Overall, the fossil chironomid fauna at Kashiru indicated long-term persistence of a cold montane peat bog with a fragmented water surface through which small streams occasionally flowed. Stratigraphic trends in the species assemblages support pollen evidence for drier conditions in equatorial East Africa during the Last Glacial Maximum (~25 000–15 000 years ago) and a fairly humid climate before that time (Bonnefille et al., 1990). *Chironomus formosipennis*, another *Chironomus* sp. and *Harnischia*, which all require mud bottoms and open standing water, are limited to the period before 25 000 years ago. Also concentrated in this section are the remains of *Chaetocladius*, which typically occur in swampy lakes, and *Rheocricotopus*, indicating some stream flow through the fen. Lowering of the water table during the Last Glacial Maximum is indicated by the prevalence of taxa resembling Holarctic genera with semiterrestrial larvae, such as cf. *Pseudosmittia* and *Bryophaenocladius*. The bog surface did not desiccate completely, however, as attested by the persistence of benthic water fleas (chydorid Cladocera) and a minority component of aquatic Chironomidae (*Polypedilum*, *Tanytarsus*, Tanypodinae indet). The onset of the postglacial Pluvial period around 15 000 years ago resulted in the disappearance of *Bryophaenocladius* and cf. *Pseudosmittia*, and a return to higher chironomid faunal diversity.

One of the best-resolved African climate-proxy records based on fossil chironomid data is that of Crescent Island Crater (1°S 36°E), a satellite basin of Lake Naivasha in the central Kenya Rift Valley (Kenya). This fossil record documents water-balance variations over the past 1100 years with decade-scale time resolution (Verschuren et al., 2000a). For this study an exploratory salinity-inference model was developed (Verschuren et al., 2004, see also below), calibrated using a compilation of published distribution data on 20 common chironomid species in 32 African surface waters (Verschuren, 1997). The resulting salinity reconstruction (Figure 1) is fully consistent with a parallel reconstruction based on fossil diatoms, and with a lake-level reconstruction based on changes in the lithological characteristics of the sediment sequence. The combined data show that equatorial East Africa was significantly drier than today during the Medieval Warm Period (~AD 1000–1270) and that fairly wet conditions during the Little Ice Age (~AD 1270–1850) were interrupted around AD 1380–1420, 1560–1620, and 1760–1840 by three decade-scale episodes of severe aridity. From ~AD 1670 to 1770, that is, the period which encompasses the Maunder Minimum in solar radiation, Crescent Island Crater stood higher than at any other time in the past millennium. The local chironomid fauna of that time was dominated by *Dicrotendipes septemmaculatus*, in line with the positive relationship between this species and lake depth in the historical (post-1880) portion of the sediment record. Presumably, this reflects expansion of its preferred habitat of submerged macrophyte beds during lake high stands. Superimposed on pronounced lake-level fluctuation during the past 1100 years is a long-term freshening trend, beginning with the transition to a more frequently positive water balance (rainfall and river inflow exceeding evaporation and loss to groundwater) after AD 1270. In the chironomid data this is reflected in the punctuated disappearance of salt-loving species

(*K. disparilis*, *Microchironomus deribae*) after each new high stand episode, to the benefit of a diverse freshwater assemblage including some salt-intolerant taxa (e.g., *Psectrocladius viridescens*).

The observation that recurrent drought is a natural characteristic of Kenya's semiarid Rift Valley climate also followed from a 200-year paleoenvironmental reconstruction at Lake Oloidien, another satellite basin of Lake Naivasha (Verschuren et al., 1999b). This study was intended to provide a long-term historical perspective on the problem of rising salinity during the late 1980s and early 1990s, and the possible role of rapidly increasing water extractions by the sprawling horticulture industry around Lake Naivasha. Fossil evidence for the historical alternation of freshwater and salt-tolerant aquatic biota (including Chironomidae) throughout the nineteenth and twentieth centuries revealed that soda-lake conditions are a natural recurrent phenomenon in Lake Oloidien, due to major natural rainfall variability combined with the dependence of Lake Oloidien on episodes of confluence with Lake Naivasha to remain fresh. The recent salinity rise was temporarily halted in early 1998, thanks to a 2.6-m lake-level rise following high rainfall driven by El Niño. However, the authors noted that diversion of river inflows for cropland irrigation and direct water extractions for the horticulture industry will increasingly limit the ability of such periodic high-rainfall events to restore confluence with Lake Naivasha, and eventually result in Lake Oloidien becoming permanently saline.

Ryner et al. (2007) reconstructed the aquatic ecosystem response of Lake Emakat (Empakaai Crater) in northern Tanzania to hydrological change associated with postglacial warming using microfossil assemblages (chironomids, diatoms, and ostracods) alongside previously published fossil pollen and carbon and nitrogen isotopic data for the same sediment sequence. Conductivity estimates for selected intervals were derived from subfossil chironomid faunas in the surface sediments of 67 lakes in tropical Africa (Eggermont et al., 2006; see also below), and suggest a slight trend of increasing salinity from ~350 $\mu\text{S cm}^{-1}$ at the start of the sequence (ca. 14 800 cal years BP) to ~530–550 $\mu\text{S cm}^{-1}$ from 13 200 to 12 600 cal years BP, to ~610 $\mu\text{S cm}^{-1}$ around 11 000 cal years BP. All but one of the freshwater Chironomidae inhabiting the lake during this period are common eurytopic taxa. Between ca. 14 800 and 14 600 cal years BP, mud-dwelling Chironomidae, mainly *Chironomus* near *alluaudi* indicate poorly developed aquatic vegetation, consistent with high lake level in a steep-sided crater basin. Reduced lake levels and an expansion of macrophytes between ca. 14 400 and 13 200 cal years BP is indicated by chironomid remains such as *Dicrotendipes fusconotatus* and *Tanytarsus formosanus*, which are both inhabitants of littoral vegetation and shredders of coarse plant detritus. Lake transgression between ca. 13 200 and 11 800 cal years BP, then again, is reflected by peak abundances of the chironomid *Cricotopus* type East Africa suggesting well-oxygenated conditions of relatively low algal production and a dynamic unvegetated shoreline. The only midge remains recovered from sediments younger than ca. 10 000 cal years BP are the halobiont species *K. disparilis* and *M. deribae*, indicating a relatively sudden transition to a strongly alkaline soda-lake environment with conductivity exceeding 6000 $\mu\text{S cm}^{-1}$. Some paleohydrological changes reconstructed for Lake Emakat are

Figure 1 Sedimentological and biological evidence for past lake-depth and salinity fluctuations in the Crescent Island Crater basin of Lake Naivasha, with episodes of pronounced drought highlighted in yellow. From left to right: lithology-inferred lake-level change over the past ~1100 years (solid and stippled line) relative to the elevation of the sill separating Crescent Island Crater from Naivasha (broken line); diatom-inferred conductivity reconstruction using the inference model of Gasse et al. (1995); chironomid-inferred conductivity reconstruction using the hybrid model of Verschuren et al. (2004); and stratigraphic distribution of selected fossil midge taxa with species sorted according to increasing conductivity optima. Orange zones indicate periods of severe aridity. Modified from Verschuren D, Cumming BF, and Laird KR (2004) Quantitative reconstruction of past salinity variations in African lakes using fossil midges (Diptera: Chironomidae): Assessment of inference models in space and time. *Canadian Journal of Fisheries and Aquatic Sciences* 61: 986–998.

in phase with lake evolution elsewhere in the region and thus apparently track broad-scale climate changes, but others reflect a more complex adjustment of the local aquatic ecosystem to temporal variations both in total annual effective precipitation and its seasonal distribution.

Eggermont et al. (2008b) used both chironomid and non-chironomid invertebrate remains to reconstruct the aquatic community response in a groundwater-fed desert lake (Lake Yoa, northeastern Chad) to Holocene desiccation of the Sahara (Kroepelin et al., 2008; Figure 2). Until at least 4800 cal years BP, Lake Yoa was a hydrologically open, deep, and dilute ($<500 \mu\text{S cm}^{-1}$) freshwater environment with diversified near-shore habitat, including submerged macrophyte beds as indicated by a species-rich chironomid fauna mainly consisting of steno- and eurytopic freshwater taxa. A distinct increase of a presumed salt-tolerant *Dicoretendipes* species around 4800 cal years BP suggests that an increasingly more negative water balance resulted in measurable evaporative concentration. By 3900 cal years BP, virtually all steno- and eurytopic freshwater chironomid taxa (*Cryptochironomus* type Tanganyika, *Procladius brevipetiolatus*, *Microchironomus* type East Africa, *Polypedilum* near *deletum*, *Cricotopus* type East Africa) disappeared. Only known salt-tolerant freshwater taxa (*Cladotanytarsus pseudomancus*) persisted, and known salt-loving taxa (*K. disparilis*) appeared for the first time, indicating that the important physiological threshold of $3000 \mu\text{S cm}^{-1}$ was crossed. The transition to a true salt-lake ecosystem ($>25000 \mu\text{S cm}^{-1}$) seems to have occurred rather abruptly around 3400 cal years BP, when the remaining salt-tolerant freshwater taxa were exterminated and new salt-loving taxa appeared (*M. deribae*, *Cricotopus* type Ounianga Kebir) to complement a strongly expanding *K. disparilis*. A fourth ecological transition seems to have occurred around 2700 cal years BP with the disappearance of the halophilic *M. deribae*, suggesting that the limit of $\sim 45000 \mu\text{S cm}^{-1}$ was crossed. Finally, the last ecological transition seems to have occurred around 1500 cal years BP (AD 600), when *Chironomus* cf. *salinarius* disappeared together with a strong expansion of *Cricotopus* type Ounianga Kebir, testifying to a renewed trend of rising salinity. Comparison with proxies tracing the evolution of the terrestrial ecosystem led the authors to conclude that although the fresh-to-saline transition of Lake Yoa occurred fairly abruptly between ~ 4100 and 3400 cal years BP, continuous inflow of fossil groundwater buffered the ecosystem against shorter-term climate fluctuations. The stratigraphic distribution of other aquatic invertebrate remains seems to support this interpretation (Figure 2).

Ryves et al. (2011) analyzed sedimentary parameters (including C/N ratios, $\delta^{13}\text{C}$ of bulk organic matter and $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ of authigenic carbonates) and biotic remains (diatoms, aquatic macrofossils, chironomids) in the sediment records from two small, nearby closed crater lakes in western Uganda (Lake Kasenda and Lake Wandakara) spanning the last 700 (Wandakara) and 1200 years (Kasenda), respectively. Subfossil head capsule concentrations in samples from Lake Kasenda were too low to permit reliable stratigraphic interpretation of the chironomid community. However, major differences in the chironomid profile of Wandakara were controlled by the dominance of *N. fractilobus* and *Dicoretendipes fusconotatus*, which have a distribution restricted to the less saline ($<1200 \mu\text{S cm}^{-1}$) African lakes (Eggermont et al., 2006).

Downcore salinity inferences were made by applying weighted-average optima from Eggermont et al. (2006; see below) to the fossil data from Wandakara, weighted by their relative abundance. The combined data suggest that Kasenda has been sensitive to climate over much of this period, and has shown substantial fluctuations in conductivity, while Wandakara has had a more muted response, likely due to the increasing dominance of human activity as a driver of change within the lake and catchment over the length of our record. Evidence from both records, however, supports the idea that lake levels were low from $\sim$ AD 700 to AD 1000, with increasing aridity from AD 1100 to 1600, interrupted by brief wet phases around AD 1000 and 1400. Wetter conditions are recorded in the 1700s, but drought returned by the end of the century and into the early 1800s, becoming wetter again from the mid-1800s. Comparison with other records across East Africa suggest that while some events are widespread (e.g., aridity beginning $\sim$ AD 1100), at other times there is a more complex spatial signature (e.g., in the 1200s–1300s, and from the 1400s–1600s). This study highlights the important role of catchment-specific factors in modulating the sensitivity of proxies, and lake records, as indicators of environmental change, and potential hazards when regional inference is based on a single site or proxy.

With surface areas between 0.04 and 5.1 km², the lakes in the studies discussed so far are sufficiently small and shallow for chironomid paleoecologists to assume more-or-less complete spatial integration of chironomid death assemblages across the lake before permanent burial. Under those conditions, if no differential preservation among taxa occurs, and the relative abundances of chironomid species and ecological groups present in the fossil assemblages will reflect the fractional distribution of various types of bottom habitat at the time of deposition. These conditions are clearly not met in larger African lakes, as demonstrated by Eggermont et al. (2007). This study investigated the within-lake variability of surface-sediment chironomid assemblages in the fairly large (~ 100 – 170 km^2 in 1983) and shallow ($Z_{\text{max}} = 5$ – 8 m) fluctuating tropical lake basin of Lake Naivasha, and compared the patterns observed with those in its two smaller satellite basins, one similarly shallow (Lake Oloidien, 5.1–5.7 km², 5–8 m), the other deep and stratified (Crescent Island Crater, 1.9 km², 14–17 m). This study showed that although sedimentation dynamics in the wind-stressed main basin of Naivasha are dominated by frequent resuspension and random sediment distribution, the near-to-offshore gradient in chironomid habitat remains imprinted on subfossil assemblages. The same is true for the African great lakes, such as Lake Victoria and Lake Tanganyika, where fossil assemblages must be taken to only represent habitat conditions close to their area of deposition at the time of their deposition, contrasting with other (distant) locations within the same lake. Indeed, Eggermont et al. (2008a) analyzed the distribution of chironomid larvae along a depth transect (0–80 m) at Kigoma Bay in Lake Tanganyika, and showed a fairly high correspondence between inferred habitat preferences of fossil and live collections. In these conditions, surface-sediment death assemblages deposited recently at various depths and microhabitats within the lake can be used as modern reference data for comparison with fossil assemblages deposited at a master core location during certain

Figure 2 Stratigraphic distribution of aquatic invertebrate remains in Lake Yoa (northeastern Chad). Taxa are arranged from left to right according to their increasing weighted-average conductivity optimum. Horizontal lines indicate invertebrate zone boundaries. Reproduced from Eggermont H, Verschuren D, Fagot M, Rumes B, Van Bocxlaer B, and Kröpelin S (2008b) Aquatic community response in a groundwater-fed desert lake to Holocene desiccation of the Sahara. *Quaternary Science Reviews* 27: 2411–2425.

times in the past. Verschuren et al. (2002) and Eggermont and Verschuren (2003) exploited this principle in their use of fossil Chironomidae as tracers of anthropogenic impact on Lake Victoria and Lake Tanganyika.

Verschuren et al. (2002) addressed the question of whether the eutrophication and water-quality loss of Lake Victoria during recent decades resulted primarily from food-web alterations following the population explosion of Nile perch (*Lates niloticus*) in the early 1980s, or alternatively from increased nutrient inputs due to large-scale agricultural conversion of its drainage basin over the past half century. Fossil chironomid assemblages extracted from a mid-lake sediment core (Figure 3) traced the evolution of deep-water oxygenation through time. To strengthen their inferences, the authors first calibrated the relationship between the fossil abundance ratio of *Procladius brevipetiolatus* to *Chironomus* nr. *alluaudi* (in this paper identified as *Chironomus imicola*) and lake depth, or more specifically the duration of seasonal bottom anoxia, which increases with depth. They did so by analyzing recently deposited chironomid death assemblages in a transect of surface-sediment samples between 48 and 68 m water depth. The core analyses revealed that the hypolimnion of Lake Victoria was adequately oxygenated year-round until about 1960. Seasonal depletion of deep-water oxygen started shortly after that time and expanded strongly in the 1970s, hence, possibly contributing to the 1980s' collapse of indigenous fish stocks by eliminating suitable habitat for deep-water cichlids. Concentration data on diatom silica in the same core profile (Figure 3) further indicated that the primary (algal) productivity of Lake Victoria had already started increasing

from the 1930s onwards, that is, well before the introduction of Nile perch, and in proportion to historical agricultural production in the Lake Victoria region. The combined data thus suggested that the eutrophication of Lake Victoria, characterized by blooms of noxious algae, is due mainly to the excess nutrient input resulting from anthropogenic landscape disturbance.

Eggermont and Verschuren (2003) used fossil chironomid remains as model organisms to investigate the impact of sediment pollution (due to agricultural soil erosion) on the benthic invertebrate fauna of Lake Tanganyika. These authors did not look at stratigraphic changes in chironomid faunal composition through time, but compared the species composition of recently buried death assemblages in bottom habitat adjacent to pristine and disturbed watersheds. The analysis involved 36 surface-sediment samples from between 53 and 189 m water depth, each representing an area of nearshore sublittoral habitat adjacent to different size classes (<10 km², 30–50 km², 50–162 km², >162 km²) of either pristine or disturbed drainages. This data set was explored with uni- and multivariate techniques to evaluate relationships between species distribution and selected environmental variables. In this analysis, water depth was used as a proxy for the oxygen regime at the sampling site, and sediment composition (organic matter and carbonate content, fractions of coarse plant debris and sand) as a proxy for local substrate and food quality. The distance to shore, the surface area of the adjacent drainage, and its land-use regime were used as proxies for the susceptibility of each particular site to excess sedimentation. The authors found that in each of the three smaller drainage size classes (of the largest size class, no pristine example remained

Figure 3 Evidence for lake-wide ecosystem change in Lake Victoria, East Africa. (a) stratigraphy of biogenic silica (mostly fossil diatoms) and dissolved silica in pore waters; the stippled zone reflects the inferred core hiatus corresponding to an unconformity in unsupported ²¹⁰Pb activity at 25 cm depth. (b) Fossil diatom stratigraphy; peak concentrations in flocculent surface muds are diatoms subject to further dissolution before permanent burial. (c) Abundance ratio of the anoxia-intolerant *Procladius brevipetiolatus* versus the anoxia-tolerant *Chironomus* nr. *alluaudi* in mid-lake fossil assemblages compared with its modern-day gradient in relation to water depth as determined by the local duration of seasonal bottom anoxia. Reproduced from Verschuren D, Johnson TC, Kling HJ, et al. (2002) History and timing of human impact on Lake Victoria, East Africa. *Proceedings of the Royal Society of London B* 269: 289–294.

Figure 4 Canonical correspondence analysis (CCA) ordination of surface-sediment chironomid faunal assemblages in 38 sublittoral bottom environments of northeastern Lake Tanganyika, East Africa, adjacent to pristine (open symbols) and disturbed (closed symbols) drainages ranging from very small ($<10 \text{ km}^2$; circles) to very large ($>162 \text{ km}^2$; squares). Excess clastic sedimentation due to human disturbance of adjacent stream drainages resulted in directional shifts in faunal composition (arrows), indicating habitat change equivalent to reductions in water depth and distance to shore. Reproduced from Eggermont H and Verschuren D (2003) Impact of soil erosion in disturbed tributary drainages on the benthic invertebrate fauna of Lake Tanganyika, East Africa. *Biological Conservation* 113: 99–109.

in the study area), catchment disturbance had resulted in similar shifts in chironomid faunal composition (Figure 4), which apparently reflected an expansion of coarse, low-organic substrates into deeper water, at the expense of the soft organic muds which normally characterize the deep-water environment. Because the area of habitable lake bottom in Lake Tanganyika is bounded by the permanent oxycline at $\sim 100 \text{ m}$ depth, these results indicated that sediment pollution is already negatively affecting oxygenated soft-bottom environments in Lake Tanganyika, and that intensifying soil erosion in its tributary drainages may eventually threaten the survival of endemic fish and mollusc species restricted to those same environments. This study established the value of chironomid death assemblages as biological indicators of ecosystem health on the scale at which human impact occurs, which is that of entire drainage basins.

Methodological Advances in African Chironomid Paleoecology

Qualitative Inferences Using the Indicator-Species Approach

Comprehensive lake surveying and collecting efforts in tropical Africa often face considerable logistical problems, sometimes

compounded by political obstacles. Consequently, until recently no large uniform reference data sets existed on the distribution of chironomid species across modern climate and ecological gradients. This obviously limited paleoecologists' opportunities for chironomid-based quantitative reconstruction of past environmental change. Existing autecological information on local species is also mostly anecdotal, and in contrast with other biological proxy indicators such as diatoms, it can be used for paleoecological inferences only when both adult and larval morphology are known. As a result, workers interpreted stratigraphic change in fossil chironomid assemblages on the basis of traditional ecological typology and genus-level autecological data transferred from the Holarctic region. Prominent in this context is *Chironomus*, a genus of which most member species in both tropical and Holarctic regions are tolerant of poor oxygen conditions (as is often associated with anthropogenic nutrient enrichment, but occurs naturally in many stratified tropical lakes). Another example is the subfamily Diamesinae, the members of which are largely restricted to cold-water environments and therefore characteristic indicators of cold climatic episodes during the last deglaciation in north-temperate Europe and North America. Fossil Diamesinae have also been reported from south-temperate New Zealand, but not yet from Africa. However, the occurrence

of at least three *Diamesa* species in alpine lakes and streams on Africa's highest mountains suggests they might become valuable tracers of tropical glacier advance and retreat.

Among chironomid-based paleoclimate research in Africa using the indicator-species approach, studies on past salinity change in lowland lakes (Mees et al., 1991; Verschuren et al., 1999b) took advantage of a fair amount of preexisting autecological information on the local species (Verschuren, 1997); the study dealing with montane peat-bog fauna (Verschuren et al., 1996) relied almost exclusively on ecological data from related Holarctic taxa.

Development of Quantitative Inference Models

Quantitative reconstruction of lake and climate history based on fossil chironomid assemblages requires calibration of the relationship between chironomid species distribution and modern environmental conditions in an appropriate number of physically, chemically, and/or ecologically diverse lakes. Initially lacking a traditional surface-sediment calibration data set where this relationship is determined using recent death assemblages of larval remains extracted from surface sediments, the first exploratory model for quantitative salinity inference (Verschuren et al., 2004) was developed using published distribution data based on regional surveys of the living fauna (adults and/or larvae). Using the computationally simple method of weighted-averaging, the authors produced inference models with a statistical performance comparable to that of weighted-averaging salinity-inference models based on African diatoms (Gasse et al., 1995). For reconstruction of lake-level change in the Kenya Rift Valley, Verschuren et al. (2000a) then performed a hybrid procedure in which this inference model, calibrated with presence-absence distributional records, was applied to abundance-weighted fossil data. This ensured that not only the appearance or disappearance of taxa but also changes in their relative abundance would generate a proxy climate signal. Because of the rather small number of calibration data (20 taxa recovered from 32 sites, or 147 species-conductivity combinations only) the model's statistical power is somewhat limited. Regression of inferred over observed conductivity in the 32 reference lakes also suggested a threshold response of African chironomid communities at the transition between freshwater and salt-lake environments ($\sim 3000 \mu\text{S cm}^{-1}$), as opposed to the more continuous species replacement along the salinity gradient seen in diatoms. To evaluate whether this does indeed reflect ecological reality, or is an artifact of the inference model due to the use of presence-absence calibration data that perhaps do not adequately cover the regional salinity gradient, Eggermont et al. (2006) constructed a true paleoenvironmental calibration data set based on percent-abundance data of 65 chironomid morphotypes recovered from the surface sediments of 67 lakes in equatorial East Africa (Kenya, Uganda, Ethiopia, and Tanzania), and then applied various numerical techniques to this calibration data set to develop a series of salinity-inference models (Figure 5(a)). These new models are evidently more statistically robust than the exploratory model developed previously, but the observed threshold response of African chironomid communities to increasing salinity remained. To improve model sensitivity, the authors experimented with modified

calibration data sets in which the regional salinity gradient was extended further (by adding dilute high-elevation lakes from Mt. Kenya and the Ruwenzori Mountains.) or in which fresh and saline lakes were represented in equal numbers (to shift upward the salinity optimum of salt-tolerant taxa). Neither experiment appreciably improved the inference models' statistical performance.

Validation of the new African chironomid-salinity inference models in the time domain, in part based on direct comparison of chironomid-inferred salinity trends with those based on fossil diatoms, revealed significant variation among models in reconstructed salinity trends through time, due to their different sensitivity to the presence or relative abundance of certain key chironomid taxa. Models based on simple weighted-averaging and the modern analog techniques were inferior to more sophisticated models (such as maximum likelihood models) on the basis of error statistics. However, these simpler models produced the most trustworthy salinity reconstructions. The authors suggested that this occurred exactly because their step change of inferred conductivity near $3000 \mu\text{S cm}^{-1}$ mirrors the rapid climate-driven transitions between fresh and saline lake phases actually happening in these shallow closed-basin lakes. In a broader context, Eggermont et al. (2006) stressed that selection of the most appropriate transfer function for environmental reconstruction using fossil chironomids (or any other biological proxy indicator) should not only compare their statistical performance, but also consider whether models produce ecologically meaningful results with high signal content.

Verschuren and Eggermont (2007) compared the performance of the above-mentioned salinity-inference models, which are all based on $>100 \mu\text{m}$ size fractions of surface-sediment fossil assemblages, with models based on the $>150 \mu\text{m}$ size fractions only. They found that despite $\sim 35\%$ additional fossil loss, restriction to $>150 \mu\text{m}$ data did not appreciably affect individual taxon optima and tolerances, and resulted in only modest reduction of mean taxon richness per lake. Parameters of statistical model performance were as good as, or better than those of models based on the $>100 \mu\text{m}$ data. Also, the application of inference models based on $>150 \mu\text{m}$ or $>100 \mu\text{m}$ data to a 200-year fossil record from Lake Abiyata, Ethiopia, produced very similar trends and amplitudes of inferred past salinity change. Using the larger mesh size reduced sample processing time by up to 50%, by removing a significant proportion of visually obstructive organic debris, and allowing a greater fraction of chironomid fossils to be identified directly in the sorting tray. The fraction of first instar group taxa in surface-sediment samples was cut from 13% to 3%, increasing the mean taxonomic resolution of fossil assemblages, and thus their ecological specificity.

Fossil assemblages of chironomid larvae are well-established paleothermometers in north-temperate and boreal regions, but their potential for temperature reconstruction in tropical regions had not been assessed until recently. Eggermont et al. (2010a) surveyed subfossil chironomid assemblages in the surface sediments of 65 (fresh) lakes and permanent pools in southwestern Uganda (including the Ruwenzori Mountains) and central and southern Kenya (including Mt. Kenya) to document the modern distribution of African chironomid communities along a regional temperature

Figure 5 African chironomid-based inference models using weighted-averaging for (a) salinity reconstruction and (b) mean annual air temperature (MATemp) reconstruction. Illustrated are the scatter plots of predicted versus observed values. Data from H. Eggermont.

gradient covered by lakes between 489 and 4575 m a.s.l. (mean annual air temperature range: 1.1–24.9 °C; surface water temperature range: 2.1–28.1 °C). Similar to the salinity trial models, the authors applied various numerical techniques to this calibration data set to develop a series of temperature-inference models, and also ran trials with subsets of lakes with varying gradient lengths of temperature and other environmental variables. All inference models calibrated against temperature produced error statistics ranking among the best when compared to similar work on other continents (Figure 5(b)). Models based on calibration over the full temperature gradient suffer somewhat from the limited number of study sites at intermediate elevation (2000–3000 m), and from the presence of morphologically indistinguishable but ecologically distinct taxa. Calibration confined to high-elevation sites (>3000 m) has poorer statistics, but is less susceptible to biogeographical and taxonomic complexities.

Testing the Response of African Chironomidae to Climate Change

Verschuren et al. (1999a, 2000b) used dated sediment records linked to long time series of historical data to investigate the operative limits of African Chironomidae as biological climate proxies. These studies employed the sediment records of satellite basins of Lake Naivasha in Kenya, which, because of their hydrological connections, have all experienced the same 120-year history of documented lake-level change. Instrumentally recorded lake depth was linked to the sediment record by ^{210}Pb dating, whereas past mixing regime, salinity, and benthic habitat conditions were reconstructed using lithological indicators, fossil diatoms, and plant macrofossils, respectively. In both studies, chironomid species-assemblage changes through time were entirely consistent with available autecological data and known salinity tolerance ranges. Salinity change and the

temporal occurrence of littoral papyrus swamp together explained about half of the historical variation in benthic community composition, and their effects appear to be largely independent from each other. Most importantly, these studies illustrated the complexity of biological response to short-term (decade-scale) water-balance fluctuations. Specifically, the direct physiological problem of osmotic stress caused by salinity change appears to affect African zoobenthos communities only at the extremes of the salinity gradient. A significant portion of the observed correlation between salinity and invertebrate community structure is in fact an indirect effect of diffuse covariance between salinity, lake level, and the distribution of various types of benthic habitat.

Eggermont et al. (2010b) assessed whether high-altitude lakes in the Rwenzori Mountains (Uganda – DR Congo) are sensitive to climate-driven environmental change of the same order of magnitude as that expected to result from current and future anthropogenic global warming. This was done by comparing the species assemblages of larval chironomid remains deposited recently in lake sediments with those deposited at the base of short cores (dated to within of shortly after the Little Ice Age) in 16 lakes. Chironomid-based temperature-reconstruction models were made using the East-African temperature-inference models mentioned above (Eggermont et al., 2010a). Excluding one atypical mid-elevation lake, the authors found a three-to-one ratio in cases of inferred warming versus cases of inferred cooling. The chironomid-inferred temperature changes mostly fell within the error range of the regional temperature-inference models, but a generalized linear mixed model analysis of the combined result from all lakes nevertheless indicated significantly warmer mean annual temperatures (on average $+0.38 \pm 0.11$ °C) at present compared to between ~85 and ~645 years ago. This result was independent of basal core age and of whether lakes were located in glaciated or nonglaciated catchments, suggesting that at least part of the

Figure 6 Subfossil remains of larval Chironomidae recovered from African lake sediments. (a) *Polypedilum* near *deletum* Goetghebuer, (b) *Conochironomus* type Gagouba, (c) *Chironomini* indet. type *Tanganyika* sp. 1., (d) *Tanytarsini* indet. type Large Hall Tarn. Photos by H. Eggermont.

signal is due to relatively recent, anthropogenic warming. Analysis of the patterns of faunal change at each lake in relation to established species–environment relationships does suggest that part of the observed shifts in species composition reflect lake-specific evolution in habitat features other than temperature, such as nutrients, pH or oxygen regime, which covary with temperature to greater or lesser extent.

Taxonomy and Biogeography of African Chironomidae

Progress in the discrimination of subfossil morphotypes of African chironomid larvae (Eggermont and Verschuren, 2004a,b, 2007; Eggermont et al., 2005, 2008a; Verschuren, 1997; Figure 6) continues to increase the taxonomic diversity of fossil assemblages. Judging from comparison with morphological diversity within and between genera in the better known Holarctic fauna, most fossil larval morphotypes currently distinguished in African contexts must be functionally equivalent to biological species, or groups of closely related species. Maintaining a strong link to official chironomid taxonomy and systematics based on the morphology of adult midges ensures compatibility between ecological data derived from living and fossil assemblages, and justifies the use of chironomid fossils as biological proxy indicators. Given this level of taxonomic resolution, the African fossil material can also be exploited to address biogeographical issues about the living fauna, such as its patterns of alpha- and beta-diversity (taxonomic richness of lakes and regions, e.g., Eggermont et al., 2005). It can also be exploited to assess the biological uniqueness of particular aquatic ecosystems in the context of biodiversity conservation. Most of all, in regions such as Africa where we have only fragmentary taxonomic and ecological knowledge of individual chironomid species, taxon-discrimination criteria based on fossil material can also improve species discrimination in the living material. If this stimulates new applied ecological research on the benthic invertebrate communities of Africa's modern aquatic ecosystems, the knowledge gained may eventually feed back into improved interpretation of

chironomid stratigraphy for the purpose of paleoenvironmental reconstruction.

Late Pleistocene of Europe

Introduction

Chironomids, nonbiting midges, are among the most versatile indicators of paleoenvironmental change. They have been used to reconstruct, both quantitatively and qualitatively, a variety of environmental variables. They have proved to be particularly useful as temperature proxies. Until the 1990s, paleoecologists used chironomids in qualitative studies of climate change. They assessed changes in chironomid assemblages, from those dominated by thermophilic taxa to those dominated by cold stenothermic taxa, as a reflection of relative changes in climate. However, with the advent of numerical techniques, which take the modern temperature optima of taxa and transfer these to fossil assemblages, it is now possible to use chironomids quantitatively to reconstruct past climatic change at high temporal resolution with an error of about ± 1.0 °C. In this article, the use of chironomids as climate proxies for sequences during the late Pleistocene in Europe is reviewed. First, papers in which chironomids were used as qualitative indicators are reviewed and then an account of studies in which chironomids have been used quantitatively to estimate changes in mean July air temperature is presented. Finally, the results of these studies are compared with results obtained from other climate proxies and the relative performance of chironomids as climate proxies is assessed.

Chironomids as Qualitative Indicators of Climate Change in the late Pleistocene

Chironomids have been used for 80 years to investigate past environmental change. However, like Gams' (1927) pioneering work, the majority of these studies have focussed on Holocene sequences. Nevertheless, among the earliest uses of chironomids in a paleoecological context was the work of Andersen (1938) who investigated a late-glacial sequence from Denmark. However, it was not until the 1970s–1980s that the Late Glacial once more became the focus of paleoenvironmental studies using chironomids, when a series of papers were published by Wolfgang Hofmann.

Hofmann (1978) found a diverse late-glacial chironomid fauna at Grosser Segeberger See in northern Germany. In this study, the Younger Dryas was dominated by cold stenothermic taxa of the *Tanytarsus lugens* community. During the Bølling, *Corynocera ambigua* comprised over 40% of the chironomid fauna. Other taxa included *Microtendipes* and *Procladius*. In several other studies (see Section 'Chironomids as Quantitative Indicators of Climate Change in the late Pleistocene'), *C. ambigua* rapidly dominates late-glacial chironomid assemblages and just as rapidly declines after a relatively short period of time. Hofmann found similar trends in late-glacial chironomid assemblages at Schöhsee (Hofmann, 1971). Insufficient data were available from the Allerød to draw any firm conclusions.

Lobsigensee, on the Swiss Plateau, was the focus of a study into the response of midge assemblages to climate change during the Late Glacial (Hofmann, 1983a). The Oldest Dryas was characterized by an assemblage dominated by *Sergentia coracina* and *Chironomus anthracinus* type. Early in this period *Microtendipes*, *Paratanytarsus*, and *C. ambigua* were also abundant, but toward the end of the Oldest Dryas these taxa declined and were replaced by *Psectrocladius*, which coincided with the establishment of *Betula nana* in the catchment. These changes are consistent with climatic warming from relatively cold conditions. The cold-adapted fauna included cold stenotherms such as *S. coracina* and *C. ambigua*, and *Microtendipes*, which is cool tolerant. This fauna was replaced by a temperate climate fauna in which the thermophilic taxon *Psectrocladius* thrived. A major change in the fauna occurred at the onset of the Bølling when the fauna became dominated by just three thermophilic taxa, namely *Microtendipes*, *Chironomus*, and *Psectrocladius*. In the Allerød, the fauna became even less diverse when 89% of the specimens were either *Chironomus* or *Tanytarsus* sp. C (Hofmann, 1971) but there was also a large increase in *Dasyhelea*, a ceratopogonid biting midge. This suggests that while temperate conditions continued to prevail, water levels in the lake also fell. The Lobsigensee core was taken in the littoral zone of the lake which would make it particularly sensitive to lake level change. Thus, changes in the chironomid fauna apparently indicated both changes from cold to temperate conditions and also a decline in precipitation. The core was sampled at relatively coarse intervals and so it was not possible to differentiate any response to relatively short-duration climatic oscillations.

In order to determine whether late-glacial climate was driving changes in chironomid assemblages at other sites, Hofmann (1983b) analyzed sediments from a littoral core from Poolsee, a shallow lake in northern Germany. Once more he found that the early late-glacial chironomid fauna was dominated by taxa such as *Micropsectra*, *Heterotrissocladius*, *Protanypus*, *S. coracina*, and *Paracladius*, which are typical of cold, oligotrophic conditions. Hofmann argued that because these taxa, which occur in the profundal zone of temperate lakes, were occurring in the littoral zone of the lake, they must be indicative of a cold climate rather than trophic conditions. These taxa were replaced by thermophilic taxa as temperature warmed in post glacial times. Similar patterns emerged from studies at other sites. The early late-glacial chironomid fauna at Meerfelder Maar, southern Germany (Hofmann, 1984), was dominated by cold stenothermic taxa such as *Diamesa*, *Paracladopelma nigrifulva*, and *Micropsectra*, but these were later replaced by taxa associated with more thermophilic conditions such as *Psectrocladius* and *Paratanytarsus*.

In a study of cores from three lakes in the Eifel region of southern Germany and a lake from the Massif Central in central France, Hofmann (1990; 1991) found that Upper Pleniglacial sediments had relatively few chironomid remains but those present in the littoral zone of lakes (*Diamesa*, *Protanypus*,

Paracladopelma, and *Micropsectra*) were all indicative of cold conditions. During the Middle-Lower Pleniglacial and Early Glacial the increase in abundance and changes in dominance between *Micropsectra* and *Paracladius* indicated that climatic conditions may have been slightly warmer. During the Eemian Interglacial increasing species diversity and the presence of thermophilic species, including *Glyptotendipes*, indicated that conditions had become considerably warmer.

At Lago Albano, central Italy, the response of chironomids to climatic change between 28 and 17 ka BP was investigated as part of a multiproxy study (Guilizzoni et al., 2000; Manca et al., 1996). Between 28 and 26 ka BP chironomids were abundant and the fauna was dominated by *Paracladopelma* and *Micropsectra*. These taxa are indicative of cool, oligotrophic conditions. From 26 to 17 ka BP, very few chironomids were recovered but most were *Micropsectra*. Numbers increased once more during the Late Glacial and the fauna became more diverse, including *Micropsectra* but in addition temperate, littoral taxa such as *Dicoretendipes* and *Cladotanytarsus* (Manca et al., 1996). Increases in the overall abundance and diversity of chironomids were probably in response to increases in temperature, while cooler, drier periods resulted in a decrease in lake productivity and thus chironomid abundance.

Brooks (2000) studied the Late Glacial–early Holocene chironomid assemblages of four lakes on an altitudinal transect in the Swiss Alps (Gerzensee, 603 m; Leysin, 1230 m; Regenmoos, 1260 m; Hérémenche, 2300 m). This was a high-resolution study, and samples were analyzed at 0.5 cm intervals in some sections of the cores, in order to detect the chironomid response to low amplitude, short-duration cold oscillations. Because the lakes were each at different altitudes they supported quite different chironomid assemblages. However, if the chironomids were influenced by regional climate change then a synchronous response would be expected in all the lakes and this could be disentangled from local responses to in-lake environmental change, which would not affect the chironomid assemblages of all the lakes at the same time. A detailed chronology was obtained by wiggle-matching high-resolution oxygen isotope records from each lake against the Greenland ice core (GRIP) oxygen isotope record. Only Gerzensee and Leysin will be considered here since late-glacial sediments were not well-represented at the other two sites. A high-resolution record was obtained from Gerzensee where the sequence between 13 440 and 11 154 cal years BP was analyzed at approximately 10–30 years intervals (Figure 1). The late Interstadial was dominated by a temperate taxon, *Parakiefferiella bathophila*, which accounted for 40–60% of the chironomid assemblage. However, during the Gerzensee Oscillation (13 200–12 800 cal years BP), there was a significant increase in the abundance of a second *Parakiefferiella* species, which later dominated the Younger Dryas assemblage. This taxon was referred to as *Parakiefferiella* type A, and is the same as *Parakiefferiella* sp. B of Walker et al. (2003). At the start of the Younger Dryas *P. bathophila* decreased abruptly, and finally disappeared in the second half of this period. It was not until the early Holocene that *P. bathophila* returned and rapidly became a dominant part of the fauna once more. This taxon was apparently close to its thermal threshold at Gerzensee and therefore, was a sensitive indicator of climatic conditions at this site. At Leysin (Figure 2) *P. bathophila* was absent. Presumably temperatures were too low at this altitude to support a

population. *Parakiefferiella* type A became more abundant again during the Gerzensee Oscillation and Younger Dryas, but at this site *Einfeldia* was apparently close to its thermal threshold and was only present in the fauna during the cold oscillations. This study clearly demonstrated that chironomids could be useful paleoclimatic indicators because they were responding to shifts in regional climate. Synchronous responses to cool oscillations, which were independently identified from an oxygen isotope signal, were apparent in each lake from different elements of the chironomid fauna. Unfortunately, despite the development of a quantitative chironomid-temperature inference model based on a modern training set of Swiss lakes (Heiri, 2001; Heiri et al., 2003) it has not been possible to estimate temperatures from either of these two sites because *Parakiefferiella* type A was not represented in the training set. This taxon is present in southern Norway today but has apparently been eliminated from the Swiss fauna since the Late Glacial.

Gandouin and Franquet (2002) described a Late Glacial and Holocene chironomid fauna from Lac Long Inférieur in south-east France. The Late Glacial was not examined in detail but the fauna during this period was dominated by *T. lugens*-type and other cold stenotherms including *Paracladius* and *Diamesa* which indicate that cool, oligotrophic conditions prevailed. A peak in the abundance of *Micropsectra* suggested a cold oscillation in the mid-Interstadial but the chronology of the sequence was not sufficiently resolved to determine which Greenland Interstadial event this may reflect. A gradual decline in *T. lugens*-type and an increase in taxon diversity throughout the Interstadial may indicate an increase in temperature. However, this is contrary to most temperature reconstructions for this period. Another possible explanation for this result may be a decrease in lake level.

A relatively new and promising development has been the analysis of stable oxygen isotopes from the chitin in chironomid head capsules. This provides the attractive potential of obtaining two independent climate records from the same proxy. Work by Wooller et al. (2004) and Verbruggen et al. (2010a) demonstrated that there was a strong relationship between chironomid $\delta^{18}\text{O}$ and precipitation $\delta^{18}\text{O}$. Verbruggen et al. (2010b) then went on to show that chironomid $\delta^{18}\text{O}$ could be used to derive a late-glacial record from Rotsee, Switzerland, which was a good reflection of the $\delta^{18}\text{O}$ record based on bulk carbonate sediments from the lake. This work demonstrates that chironomids can be used to produce a $\delta^{18}\text{O}$ record from lakes on carbonate-poor bedrock and low in organic material, thus significantly expanding the number of lake sediment records that can be studied for variations in past lake water $\delta^{18}\text{O}$. However, Verbruggen et al. (2010b) caution that more information is required on the extent to which chironomid $\delta^{18}\text{O}$ is influenced by temperature before the technique can be used as a reliable temperature proxy.

Chironomids as Quantitative Indicators of Climate Change in the late Pleistocene

The development of quantitative chironomid-mean July air temperature inference models has revolutionized paleoclimate research. Now it is possible to obtain high resolution, low error, summer air temperature estimates from lake sediment

Figure 1 Response of Chironomidae to climate change around the time of the Younger Dryas at Gerzensee, Switzerland. GO, Gerzensee Oscillation; PBO, Preboreal Oscillation; YD, Younger Dryas. Reproduced from Brooks SJ (2000) Late-glacial fossil midge stratigraphies (Insecta: Diptera: Chironomidae) from the Swiss Alps. *Palaeogeography, Palaeoclimatology, Palaeoecology* 159: 261–279.

samples with the knowledge that the biological proxy has completed its development *in situ*. At the sampling resolution of most studies, the response of midge taxa to climate change shows little or no delay by virtue of the long-distance, wind-assisted, rapid dispersion of chironomid adults across the landscape. These chironomid-inferred temperature reconstructions can be compared with high resolution oxygen isotope records and quantitative reconstructions based on other proxies such as pollen and beetle assemblages to confirm their reliability.

The first late-glacial chironomid-inferred summer temperature records from Europe were published as part of a multiproxy study of Kråkenes Lake, western Norway (Brooks and Birks, 2000a). The chironomid-inferred temperatures were derived from a modern Norwegian 44-lake training set. The training set covered a mean July air temperature range of 5.7–14.0 °C but in fact only two lakes in the training set experienced mean July air temperatures of less than 8 °C and so the chironomid-inferred temperatures estimates derived from this model were likely to

overestimate the coldest temperatures of the Younger Dryas. Details of the chironomid stratigraphy are shown in Figure 3. The early Interstadial chironomid fauna was dominated by cold stenothermic taxa such as *Diaesinae*, *Heterotrissocladius grimshawi*, *T. lugens*-type, *Micropsectra radialis*, *S. coracina*, and *Arctopelopia* but also included more temperate taxa such as *Cricotopus*, *Psectrocladius sordidellus*-type, and *Microtendipes*. As the Interstadial climate continued to warm, the proportion of temperate taxa increased at the expense of the cold stenotherms, and *Diaesinae* disappeared from the fauna altogether. The onset of the Younger Dryas caused a sudden and major change in the chironomid fauna. The temperate taxa and some of the cold stenothermic taxa, such as *Sergentia*, *T. lugens*-type, and *Arctopelopia* were eliminated. *M. radialis* and *H. grimshawi* continued to dominate the fauna, *Diaesinae* returned, but several cold stenothermic taxa appeared in the fauna for the first time, including *H. subpilosus* and *Paracladius alpicola*. These faunal changes indicate that the lake went from cool, mesotrophic to very cold and ultraoligotrophic conditions.

Figure 2 Response of Chironomidae to climate change around the time of the Younger Dryas at Leysin, Switzerland. GO, Gerzensee Oscillation; PBO, Preboreal Oscillation; YD, Younger Dryas. Reproduced from Brooks SJ (2000) Late-glacial fossil midge stratigraphies (Insecta: Diptera: Chironomidae) from the Swiss Alps. *Palaeogeography, Palaeoclimatology, Palaeoecology* 159: 261–279.

Mean July air temperatures of 9–10 °C were inferred from the chironomid assemblage for the Younger Dryas which were about 5 °C higher than those inferred from plant macrofossils. This indicated that the range of temperatures covered by the chironomid training set was not sufficient to reconstruct reliable temperatures for the late-glacial period. Therefore, an additional 65 lakes were added, which extended the range of temperatures in the modern training set to 3.5–15.6 °C, and in addition provided a more even distribution of lakes across the temperature gradient (Brooks and Birks, 2001). Using the expanded training set, new temperature estimates for the Late Glacial and early Holocene were obtained that closely supported the temperatures indicated by the plant macrofossils (Figure 4).

Gradually warming temperatures from about 9.5 to 10.5 °C are indicated during the Interstadial, followed by a sudden drop of about 3.5 °C over a 60-year period at the start of the Younger Dryas. This fall is still not as great as that inferred from vegetational changes which suggest that temperatures fell by as much as 6 to 4–5 °C (Birks, 1994). Chironomid-inferred temperatures began to increase before the end of the Younger

Dryas, shortly after 12 000 cal years BP, and continued to rise rapidly into the early Holocene.

The 109-lake Norwegian training set was also used to reconstruct late-glacial temperatures at Whitrig Bog in southeast Scotland (Brooks and Birks, 2000b; 2001). High resolution analysis of the core meant that a highly detailed picture of climatic fluctuations emerged. Following the deglacial period when the chironomid assemblage was dominated by cold stenotherms, the Interstadial fauna was dominated for the most part by temperate taxa such as *Psectrocladius*, *Chironomus*, *Tanytarsus* spp., and *Pentaneurini* (Brooks et al., 1997). However, there were two relatively short periods when there was a resurgence of cold-water taxa. In the earliest period, eight cold taxa were present and there were declines in most of the temperate taxa, including *Chironomus* (Figure 5). During the second cool period only three cold-water taxa were present and, although several temperate taxa declined, *Chironomus* did not decline in abundance. At the onset of the Younger Dryas there was a sudden replacement of the entire temperate fauna by a cold water fauna, dominated by *M. radialis*-type, which had not previously occurred in the lake, and several

other taxa which had only occurred at low abundance during the previous cold periods. These faunistic changes implied that the Younger Dryas was the coldest period in the Late Glacial, that temperatures during the early cool oscillation were a little less cold, but that they were considerably colder than the second cool oscillation.

These qualitative inferences were confirmed when the 109-lake Norwegian transfer function was applied to the data. Interstadial mean July air temperatures gradually fell from ~ 11.5 to 11.0 °C but were punctuated by two major cold oscillations. During the first oscillation, temperatures fell to ~ 8.0 °C. This oscillation is referable to Greenland Interstadial event 1d (GI-1d) which has been recorded in northern Switzerland as the Aegelsee Oscillation (Lotter et al., 1992) and elsewhere in Europe (Björck et al., 1998). The second oscillation, when temperatures fell to ~ 10.0 °C, is referable to Greenland Interstadial event 1b (GI-1b) and has

also been recorded elsewhere in Europe as the Gerzensee or Amphi-Atlantic Oscillation (Bedford et al., 2004; Levesque et al., 1993; Lotter et al., 1992). Early in the Younger Dryas, temperatures fell to ~ 7.5 °C but gradually increased to ~ 8.5 °C at the end of this period. These trends are closely reflected in the GRIP ice core oxygen isotope record (Figure 6), in particular, the gradual warming during the Younger Dryas, the two major cold oscillations in the Interstadial, together with the suggestion of two additional minor Interstadial oscillations just before and just after GI-1d. However, there are two obvious differences between the records. First, the cooling trend in Interstadial temperatures is more pronounced in the ice core record than the Whitrig Bog record. Second, GI-1d is warmer than GI-1b in the GRIP record, whereas at Whitrig Bog the reverse is indicated. The chironomid-inferred temperature estimates are closely corroborated by temperature estimates derived from plant macrofossils

Figure 6 Comparison of (a) chironomid-inferred mean July air temperatures for the Late Glacial at Whitrig Bog, southeast Scotland and (b) the oxygen isotope record from the Greenland (GRIP) ice core (Johnsen et al., 1992). Reproduced from Brooks SJ and Birks HJB (2000) Chironomid-inferred Late-glacial air temperatures at Whitrig Bog, southeast Scotland. *Journal of Quaternary Science* 15: 759–764.

(Birks, unpublished; Conolly, 1961; Sheldrick, 1997), although warmer than those derived from glacial data (Ballantyne, 1989; Sissons, 1979; Sutherland, 1984) for lowland Scotland. However, late-glacial beetle-inferred estimates for southern Scotland are consistently about 2 °C higher than the

chironomid estimates (Atkinson et al., 1987; Coope and Lemdahl, 1995; Coope et al., 1998). Reasons for this discrepancy are not obvious but may be related to differences in the response of aquatic and terrestrial insects to temperature or in the numerical approaches used to derive temperatures.

A second British quantitative reconstruction of late-glacial temperatures based on chironomids is available from Hawes Water in northwest England (Bedford et al., 2004). The chironomid assemblage (Figure 7) is similar to that of Whitrig Bog, even though Hawes Water is a hard water lake whereas Whitrig Bog has soft water. The Interstadial is once more dominated by temperate taxa such as *Microtendipes*, *Chironomus*, *Psectrocladius*, and *Pentaneurini*. However, there are two periods during the Interstadial in which the cold stenotherm, *Sergentia*, increases in abundance. The Younger Dryas is dominated by a cold water fauna very similar in composition to that at Whitrig Bog. The main difference between the two assemblages is that *C. ambigua* is most abundant during the Younger Dryas at Hawes Water, whereas at Whitrig Bog this taxon reaches maximum abundance during the Allerød. This may reflect in-lake differences between the sites since *C. ambigua* is often associated with charophyte beds (Brodersen and Lindegaard, 1999). The Norwegian training set was used to reconstruct chironomid-inferred temperatures. Interstadial mean air July temperatures gradually fell from ~13.0 to 12.0 °C but were punctuated by two abrupt cold oscillations. The first, when temperatures fell by about 2 to ~11.0 °C was more severe than the second when temperatures fell by about 1 to ~11.5 °C. Temperatures fell rapidly at the start of the Younger Dryas to ~7.5 °C but then gradually increased to ~9.5 °C at the end of this period. The chironomid-inferred temperature trend at Hawes Water therefore closely reflects that inferred at Whitrig Bog. The main difference is that temperatures are consistently warmer at Hawes Water than Whitrig Bog, but this probably reflects the more southerly location of the former site. An oxygen isotope record is also available from Hawes Water (Figure 8) and this closely matches the chironomid-inferred trends. Notably, the Hawes Water isotope record, like the chironomid-inferred temperature records, indicates that the Aegelsee Oscillation was colder than the Gerzensee Oscillation and that there was only a gradual long-term cooling trend during the Interstadial. These trends are also similar to the oxygen isotope record from Ammersee in southern Germany (Von Graffenstein et al., 1999) but differ from the GRIP record.

Additional late-glacial studies have recently been published from England (Lang et al., 2010) and Ireland (Watson et al., 2010), and others from Scotland and Norway are currently in progress by Brooks and coworkers which will be published over the next few years. All these records show similar trends as those described above and further support the view that there are important and consistent differences in detail between the Greenland oxygen isotope records and chironomid-inferred temperature records and isotope records from Europe.

Following a detailed account by Millet et al. (2003) of the late-glacial chironomid fauna at Lac Lautrey (Jura, eastern France), the Swiss chironomid-temperature inference model (Heiri, 2001; Heiri et al., 2003) was used to reconstruct Late Glacial mean July air temperatures at this site by Heiri and Millet (2005). This high resolution record (Figure 9) begins at about 16000 cal years BP when the fauna was dominated first by the cold stenotherm *Stictochironomus* and then by *C. ambigua* and mean July air temperatures were inferred at about 11–12 °C (Figure 10). There was an abrupt rise in

temperature to 14.5 °C at the beginning of the Bølling (14600 cal years BP) when a diverse fauna of widely distributed and lowland taxa replaced the alpine and subalpine fauna. During the second half of the Bølling (14200–13700 cal years BP), temperatures continued to rise more gradually to reach 16.5 °C as temperate taxa increased in abundance. These estimates are within the range of pollen-based reconstructions from central Europe (Renssen and Isarin, 2001). There was no apparent response to the Aegelsee cool fluctuation (at ca. 14000 cal years BP), however, two centennial-scale cold oscillations of 1.5–2.0 °C were indicated at 13200 and 12900 cal years BP which appear to be synchronous with the beginning and end of the Gerzensee Oscillation. Interstadial mean July air temperatures peaked at about 18 °C toward the end of the Allerød, which is warmer than present-day values from northern Switzerland and considerably warmer than late Allerød temperatures inferred from Cladocera and pollen assemblages (Lotter et al., 2000).

Mean July air temperatures declined to 14 °C at the start of the Younger Dryas but then gradually increased and were about 1 °C higher by the end of the Younger Dryas, which reflects the trends in other European records (Brooks and Birks, 2000b; Von Graffenstein et al., 1999). When corrected for altitude, the Lac Lautrey Younger Dryas estimates agree closely with chironomid-inferred records from the northern Swiss Alps (Heiri et al., 2003) but are warmer than pollen-inferred estimates (Lotter et al., 2000). A warming of about 1.5 °C was indicated at the Younger Dryas/Holocene transition, which is in close agreement with other proxy records from the region (Heiri et al., 2003; Lotter et al., 2000; Magny et al., 2001). The Lac Lautrey temperature record differs in detail from the GRIP oxygen isotope record but shares similarities with the Ammersee isotope record from southern Germany (Von Graffenstein et al., 1999). Most notably, chironomid-inferred temperatures before the Bølling warming were cooler than those during the Younger Dryas, there is a two-step increase in early Bølling temperatures, the GI-1d event is not clearly reflected in the records and there is not a strong temperature decline during the Interstadial.

Heiri et al. (2007) reported a late-glacial chironomid record from Hijkermeer, The Netherlands. Both the GI-1d and GI-1b cold oscillations are apparent in the Hijkermeer sequence, however, the temperature decline is greater during GI-1b than GI-1d, which is the opposite of the trends in the British records. The Hijkermeer record also indicates that peak Interstadial temperatures were reached after the GI-1d oscillation, at around 13.5 ka BP, which also reflects the results found at Lac Lautrey and in the Ammersee oxygen isotope record. This is later than the British records in which peak temperatures are reached early in the Interstadial, before the GI-1d oscillation. Similar trends to those at Hijkermeer are also apparent in two further records from central Switzerland, one from the Maloja Pass (Ilyashuk et al., 2009) and the other from Egelsee (Larocque-Tobler et al., 2010). However, a record from Lago Piccolo di Avigliana in the southwest Alps (Italy; Larocque and Finsinger, 2008) indicates that the warmest Interstadial temperatures occurred prior to the GI-1d cold oscillation. These records suggest that there were differences in the spatial patterns of late-glacial temperature trends across Europe, as inferred from fossil beetle records from this interval (Coope

et al., 1998), although more data is required to clarify the apparent discrepancies between them and confirm whether or not there are consistent regional patterns.

Conclusion

At present relatively few quantitative chironomid-inferred temperature reconstructions are available from the Late Glacial in Europe. However, it is clear from those that have been published that such sequences can provide valuable high resolution, low error records of climate change during this period. The chironomid-inferred temperature trends largely reflect those derived from oxygen isotope records, which suggests that the chironomid records are reliable, and so provide

quantitative details of short-lived, small amplitude climate fluctuations as well as long term trends. However, differences between the GRIP oxygen isotope record and the isotope records from Hawes Water and Ammersee are also reflected in the chironomid-inferred temperature records from Whitrig Bog, Hawes Water, Hijkermeer, and Lac Lautrey, which more closely resemble the local isotope trends than the GRIP record. This suggests that climate change was not uniform throughout the North Atlantic region and central Europe and that it may be simplistic to rely on the GRIP ice core record to provide an 'event stratigraphy' for the whole region (Björck et al., 1998). Similarly, late-glacial chironomid-inferred temperature estimates are largely corroborated by estimates derived from other proxies. Where conflicts do exist there are currently insufficient records to resolve them. Therefore, it is particularly

important that more chironomid-derived climate records become available, which will help to underline consistencies and inconsistencies between them and other proxy records. This will be necessary to improve our understanding of the limitations of the different proxy records. In particular, discrepancies between chironomid- and beetle-inferred estimates need to be resolved. However, the current lack of same site quantitative reconstructions that include both beetles and chironomids impedes the resolution of this problem.

Introduction

The Chironomidae (nonbiting midges) are a family of the Diptera (true flies) whose larvae are abundant in most freshwater habitats (Figure 1). Individual lakes can include more than 100 different chironomid species, many of which have a restricted distribution with respect to water chemistry parameters (e.g., nutrient condition, oxygen, pH) or temperature. The strongly sclerotized larval head capsules of chironomids preserve well in lake sediments and remain identifiable, usually to species-group or genus level. Therefore, past changes in the chironomid fauna of individual lakes can be reconstructed based on the fossil record preserved in sediment cores. The lacustrine environment in which different fossil chironomid ‘morphotypes’ (or taxa) occur can be assessed by analyzing the taxonomic composition of chironomid assemblages in the surface sediments of lakes. Commonly, the surficial 1 cm of sediment will be analyzed in each lake, with the samples usually originating from the lake center. These samples incorporate chironomid remains deposited within the past few years to a few decades at most and provide an integrated picture of the chironomid taxa inhabiting a lake. Surface-sediment samples analyzed from lakes with different limnological conditions indicate that, even though the remains of many chironomids cannot be identified to species level, most taxa identifiable in fossil assemblages provide useful indications of past environmental conditions.

In Europe, fossil chironomid remains from postglacial lake deposits have increasingly been used as paleoecological and paleoenvironmental indicators. They are now used as proxy indicators to assess the natural development of lakes, the effect of pollution on lake ecosystems, and quantitative reconstruction of temperature, dissolved oxygen, chlorophyll *a*, total phosphorous, lake depth, stream flow, and distance to littoral vegetation. In addition, the stable oxygen isotope composition of chironomid head capsules has been used to reconstruct past variations in lake water $\delta^{18}\text{O}$ as a proxy for temperature changes. Here, we focus on four research themes: (1) the natural development of lakes, (2) the effects of pollution on lake ecosystems and the reconstruction of past changes in water quality, (3) the reconstruction of summer temperatures during the past 11.5 ka, and (4) the effect of past environmental conditions on the down-core chironomid assemblages.

Reconstructions of Lake Ontogeny

The use of chironomids as a proxy for past environmental conditions originates from the pioneer work of August Friedrich Thienemann (1882–1960). Thienemann studied the biota of lakes in relation to physical lake characteristics. He found that lakes can be classified according to the chironomid fauna where

certain taxa are likely to occur under a certain set of environmental conditions (Thienemann, 1954). Early applications of fossil chironomid analysis were built on this work. Lacustrine chironomid records were mainly intended to reconstruct changes in lake nutrient- and oxygen conditions related to the natural development of lake ecosystems. Since chironomids were considered a key indicator group for the classification of lakes according to their trophic state, fossil chironomid records were used to explore and test hypotheses related to lake ontogeny (i.e., lake origin and development). Examples include the natural eutrophication of lakes, decreasing hypolimnic oxygen conditions in lakes as a consequence of lake infilling, and the effects of natural acidification on lake ecosystems (see Walker, 1987 for an extensive review of these topics). Although most of these studies originate from the early days of chironomid-based paleoenvironmental reconstruction, chironomids are still used to reconstruct the natural development of lakes. Some studies quantitatively interpret chironomid stratigraphy using transfer functions to infer environmental conditions and also qualitatively to interpret lake ontogeny. For example, Ilyashuk et al. (2005) studied the postglacial chironomid stratigraphy at Lake Berkut, southern Kola Peninsula, Russia. These chironomid assemblages were used to quantify postglacial temperature changes, and in addition, the ecological demands of individual taxa formed the basis for a qualitative interpretation of the lake's ontogeny in terms of changes in lake-level, hypolimnic oxygen and acidification (Figure 2).

Effects of Pollution on Lake Ecosystems and Reconstruction of Water Quality

Modern assessment of pollution and monitoring of aquatic ecosystems are often based on reference conditions, as indicated by the biota. The reference condition is defined as the observed values of biological variables in the absence of significant human impact. A restoration goal can therefore be defined on the basis of knowledge of the present and past conditions before the onset of human influence. Fossil chironomid records have been used to reconstruct and assess the effects of human-induced nutrient pollution on benthic macroinvertebrate assemblages in lakes. One commonly used approach is to analyze chironomids in the framework of a multiproxy study, usually including analyses of a number of other biotic and abiotic indicators. Changes in chironomid assemblages are then examined in view of the ecology of the chironomid taxa found and in the context of the pollution history of the lake as inferred by the other proxy records analyzed in the same sediment core. In Europe, chironomids have been widely used to study the response of eutrophication and acidification (Bítušík et al., 2009; Heiri and Lotter, 2003;

Figure 1 (a) Coring of lacustrine sediments in Norway from the lake ice surface using a Nesje piston corer (picture by G. Velle); (b) imago of *Chironomus anthracinus* male (picture by K.P. Brodersen); (c) larvae of *C. anthracinus* where the arrow indicates the head capsule (picture by K.P. Brodersen); (d) chironomid head capsule (*Cricotopus* spp. B), the heavy sclerotized mentum (me) and the mandibles (ma) are important characters for the identification of subfossil larvae (picture by G. Velle); (e) subfossil head capsule (*Micropsectra* spp.) where many of the mouth-parts have been lost, as is often the case for subfossil material (SEM picture by K.P. Brodersen).

Henrikson et al., 1982; Ilyashuk et al., 2003). For example, Meriläinen and Hamina (1993) analyzed subfossil chironomid assemblages in a sediment core from Lake Päijänne, southern Finland, encompassing the past ~150 years. Based on the identified chironomid taxa, these authors calculated the benthic quality index (BQI), a semiquantitative water-quality index defined for living chironomid assemblages in deep stratified lakes (Wiederholm, 1980), in order to trace the local eutrophication history of the lake (Figure 3). The results from Meriläinen and Hamina (1993) indicate that the studied sub-basin of Lake Päijänne experienced the strongest phase of eutrophication during the 1970s when *Chironomus anthracinus* increased in abundance, and that the trophic status of the lake has slightly improved since.

Often, the pollution history of a lake can be further constrained by using other sources, for example, published water-sampling series or historical records. If the surface sediment

layers can be adequately dated (e.g., using ^{137}Cs or ^{210}Pb dating), the down-core chironomid record can be directly compared with instrumental measurements, or records of past industrial pollution. In the case of the chironomid-based reconstruction from Lake Päijänne, Meriläinen and Hamina (1993) were able to show that during the period of highest pollution, the deterioration of the water quality as indicated by the BQI was in close agreement with the biochemical oxygen demand (BOD) of discharge from pulp mills located close to the lake basin where the sediment core was taken. However, BQI values tended to lag changes in BOD-loading by several years (Meriläinen and Hamina, 1993). In a later study, Verbruggen et al. (2011) used the relationship between the BQI and nutrient concentrations apparent in European lakes to produce a quantitative estimate of past changes in concentrations of total phosphorus (TP) in Lake Päijänne, based on Meriläinen and Hamina's (1993) results. This reconstruction agreed closely with measurements of TP available from historical sources. When using reference conditions as a restoration goal, correct estimation and validation of the reference conditions are critical. Jyväsjärvi et al. (2010) assessed whether reference conditions for Finnish lakes defined from modern studies agreed with the preimpact state as assessed by the BQI from fossil chironomid assemblages. The authors compared the performance of different numerical approaches for defining the reference states in 73 semipristine lakes. They concluded that a regression model taking into account morphometric characteristics of lakes outperformed assigning undisturbed reference conditions based on the environmental characteristics of the lakes.

During recent years, transfer functions have been produced that directly relate water-quality variables such as chlorophyll *a*, TP, or oxygen to subfossil chironomid assemblages from surface sediments of lakes (see Brodersen and Quinlan, 2006 and references therein). Down-core applications of water-quality inference models have provided promising results, but the inference models and results arising from them need further validation (see below).

Chironomid-Based Summer Temperature Reconstruction

Fossil chironomids have received by far the most attention in recent years as quantitative paleotemperature indicators. Along long temperature gradients in temperate and subarctic latitudes in Europe, the distribution of chironomid taxa in lake surface sediments is closely related to summer air- and water temperature. Hence, chironomid-temperature transfer functions can be developed that predict temperature with a prediction error typically in the range of 1–1.5 °C. At present, chironomid-summer air or water temperature transfer functions are available from different regions in Europe, including Finland (e.g., Olander et al., 1999), northern Sweden (e.g., Larocque et al., 2001), Norway (e.g., Brooks and Birks, 2001), the Swiss Alps (e.g., Heiri and Lotter, 2010), and Iceland (Langdon et al., 2008). Chironomids have been used to reconstruct postglacial temperatures at a number of sites in Scandinavia, Spitsbergen, the British Isles, Iceland, southern France, the Kola Peninsula, central Spain and different regions in the Alps. Chironomid-based temperature reconstructions have shown

Age (cal years BP)	Chironomid zone	Lake conditions			Climatic conditions			
		Avg VWHO (mg O ₂ ·l ⁻¹)	pH status	Lake level change	Humidity	Tjul (°C)		
0	CZ-III	<2.0	Acidic		High	Increasing from 11.3 to 12.2		
1000		3.5–2.0						
1500						CZ-II	3.5–4.5	Circumneutral
2400	Low	Decreasing from 12.1 to 11.3						
3500			Increasing from 11.8 to 12.1					
4000		Significant lowering		~11.8

Figure 2 Chironomid-inferred climatic and environmental changes at Lake Berkut, Kola Peninsula. VWHO refers to average ‘end-of-summer’ volume-weighted hypolimnetic oxygen. Reproduced from Ilyashuk EA, Ilyashuk BP, Hammarlund D, and Larocque I (2005) Holocene climatic and environmental changes inferred from midge records (Diptera: Chironomidae, Chaoboridae, Ceratopogonidae) at Lake Berkut, southern Kola Peninsula, Russia. *The Holocene* 15: 897–914.

great potential for inferring past summer temperature during the major climatic fluctuations during the Late Glacial period. For some postglacial sites, chironomids have provided excellent results when evaluated against instrumental temperature records from meteorological stations or against tree-line fluctuations. For example, Larocque-Tobler et al. (2010) used chironomids to reconstruct temperatures from varved sediment with near-annual resolution at Lake Silvaplana in the Swiss Alps. First, the chironomid-inferred temperatures were validated against instrumental data of the last 150 years (Figure 4). Then, the reconstructions from the last 420 years were validated with local and regional reconstructions based on other proxies. And finally, encouraged by the promising results from the first studies, chironomids were used to reconstruct temperatures for the last 1000 years (see Larocque-Tobler et al., 2010 and references therein). The reconstructed temperatures indicate that the last part of the ‘Medieval Climate Anomaly’ (ca. AD 1032–1262), was 1 °C warmer than the climate reference period (1961–90).

Further, that the ‘Little Ice Age’ was separated into three cold phases that were about 1 °C colder than the reference period (Larocque-Tobler et al., 2010; Figure 4).

Several chironomid records have been described that support that, as in the Lake Silvaplana record, chironomid assemblages can respond to summer temperature changes smaller than the prediction error of available chironomid–temperature inference models. It is therefore tempting to interpret even relatively small amplitude changes in chironomid-inferred temperature. At the same time, several examples are available which demonstrate that fossil chironomid assemblages can be strongly influenced by factors unrelated, or only very indirectly related to climate, such as human activity or large scale vegetation changes. At least some chironomid records have been developed which also clearly demonstrate that such changes in catchment or in-lake environmental conditions can lead to biases and unrealistic variations in chironomid-based temperature estimates (Heiri and Lotter, 2003), although

Figure 3 Relative abundance of selected fossil chironomid taxa and *Chaoborus flavicans* mandibles (as accumulation rates) in the uppermost sediments of Lake Päijänne, south Finland. The benthic quality index (BQI) was calculated for individual samples based on the fossil chironomid assemblages. Data and BQI values from Meriläinen JJ and Hamina V (1993) Recent environmental history of a large, originally oligotrophic lake in Finland: A palaeolimnological study of chironomid remains. *Journal of Paleolimnology* 9: 129–140.

these biases do not usually seem to exceed the prediction error of the applied transfer functions. As a consequence, opinions differ concerning the extent to which chironomid-based temperature records should be used to reconstruct postglacial climate change and whether temperature changes within the prediction error of the models should be interpreted without additional independent evidence to support these inferences.

The study of Velle et al. (2005) exemplifies some of the problems that can be encountered when applying chironomid-based temperature reconstruction to postglacial records. These authors used a chironomid–July air temperature transfer function to infer past temperature change from six postglacial chironomid profiles. There were differences in the chironomid-inferred temperature development between the six records. They concluded that these discrepancies are either related to different microclimates at the study sites, to a different

sensitivity of the chironomid fauna of the individual lakes to changes in summer temperature, or to chronological uncertainties (see Figure 5). In another study from Norway, Brooks (2003) presented a chironomid-based summer temperature record from Holebudalen, southern Norway. In this reconstruction, a distinct cooling in inferred July air temperature of $\sim 1.2^{\circ}\text{C}$ is reconstructed at ca. 8.3 cal ka BP (Figure 6). This cooling most likely represents the 8.2 ka cooling event and is clearly expressed in the chironomid-based temperature reconstruction. However, the episode is accompanied by only comparatively minor changes in the chironomid fauna (Figure 6). Brooks (2003) indicates that this decrease in inferred temperatures is largely driven by the absence of *C. anthracinus* type from the fossil chironomid assemblages at ca. 8.3 cal ka BP, a taxon at present restricted to comparatively warm Norwegian lakes.

In Swedish and Finnish Lapland, a number of Holocene temperature reconstructions have similarly been developed

Figure 4 Top: Chironomid-inferred mean July air temperatures in Lake Silvaplana (Switzerland) at near-annual resolution and instrumental temperature measurements. Modified from Larocque I, Grosjean M, Heiri O, Bigler C, and Blass A (2009) Comparison between chironomid-inferred July temperatures and meteorological data AD 1850–2001 from varved Lake Silvaplana, Switzerland. *Journal of Paleolimnology* 41: 329–342. London: Arnold; Velle G, Brooks SJ, Birks HJB, and Willassen E (2005) Chironomids as a tool for inferring Holocene climate: An assessment based on six sites in southern Scandinavia. *Quaternary Science Reviews* 24: 1429–1462.

using two different chironomid–temperature transfer functions (Korhola et al., 2002; Larocque and Hall, 2004; Seppä et al., 2002). All three reconstructions from northern Sweden (Larocque and Hall, 2004) and one record from Finnish Lapland (Seppä et al., 2002) show a more-or-less continuous summer temperature decrease from 9 cal ky BP to the present (Figure 5). This would be expected for high northern latitudes during the mid- and late Holocene due to a decrease in summer insolation in this region related to orbital changes. The second chironomid-based summer temperature record from Finnish Lapland also indicates higher temperatures at ca. 9 ka BP than at present (Korhola et al., 2002). However, it also features periods of distinctly cooler inferred temperatures between ca. 6 and 4 ka BP and, depending on the numerical method used for the transfer function, possibly another cooling episode at ca. 3–2 ka BP. These coolings are not expressed as distinctly in the other chironomid-based temperature reconstructions from northern Fennoscandia, and it is difficult to decide whether these cold episodes in one of the five records are related to regional differences in postglacial climate in northern Scandinavia, whether they reflect biases related to the use of

different numerical methods and transfer functions, or whether they are the consequence of factors other than temperature that may have influenced the chironomid assemblages.

Causative Environmental Cues for the Postglacial Chironomid Communities

Environmental reconstruction should be examined within the context of the prediction error of the inference model and the sample-specific error estimates. If the influences of confounding variables exceed the reconstruction error, then the reconstruction could be compromised. The interest in chironomids as quantitative indicators of past temperature change has therefore also led to increased research on nonclimatic factors affecting fossil chironomid assemblages. Since temperature variations in the postglacial period are smaller than in the earlier glacial periods and often of a similar magnitude as the prediction errors of the applied transfer functions, much research on nonclimatic factors has focused on the postglacial period. Velle et al. (2010b) discussed how changes in lake

catchments and lake water chemistry can influence the postglacial development of chironomid assemblages. For example, natural changes in catchment vegetation and soils can affect nutrient conditions in lakes. As discussed above, chironomid assemblages react to changes in lake trophic state. It can therefore be expected that natural changes in lake primary productivity in the past may have affected fossil chironomid records and also influenced the temperature reconstruction, given that temperature and productivity shift independently (Figure 7). Similarly, vegetation changes, especially on acid bedrock, can affect pH and dissolved organic carbon concentrations of lake water and thereby affect the chironomid faunal composition of a lake. Some open questions remain, however: (1) How strongly are chironomid-based temperature records affected by such water chemistry changes; (2) How widespread are the effects of past water chemistry changes on postglacial chironomid records (e.g., with respect to geological or climatic conditions); and (3) Are chironomid records from different lake types affected to the same extent by past changes in water chemistry, productivity, or other potentially confounding factors?

The examples discussed above indicate that it is important to take into account the ecological preferences of the taxa involved when performing environmental reconstructions. Also, consider the appropriateness of the training set involved, especially when interpreting relatively small temperature changes inferred from chironomid assemblages. For example, in a study from Anterne in the French Alps, Millet et al. (2009) used chironomids to reconstruct temperatures during the last two millennia. A comparison with other temperature records in the region suggested that temperatures were successfully reconstructed, apart from the last hundred years. This period was marked by a peculiar fauna coinciding with diverging temperature patterns compared to other climate records. The fauna was notably characterized by the disappearance of *Procladius*, a genus with a warm temperature optimum compared with other taxa in the record. Arctic char (*Salvelinus alpinus*) was introduced into the lake in 1905 and the authors link the disappearance of *Procladius* with fish predation. In another study, Velle et al. (2005) reported a phase with dominance of *C. anthracinus* type during the early Holocene in Norway coinciding with what seemed to be markedly high-inferred temperatures. The authors interpreted this phase as reflecting (1) warm temperatures, (2) high production, (3) oxygen depletion, (4) lack of competition as *C. anthracinus* type then may thrive under suboptimal temperatures, or (5) a high feeding efficiency giving the taxon a competitive advantage in nutrient poor sediments. In a study from Stora Vidarvatn in northeast Iceland, Axford et al. (2009) compared the results from a temperature reconstruction based on a chironomid-temperature training set and that of the detrended correspondence analysis (DCA) sample scores to a 170 year instrumental temperature record. They found that the DCA scores were useful for inferring past temperatures at this site and that the chironomid-temperature transfer function developed for northwestern Iceland did not perform very well in reconstructing instrumental temperature shifts. The poor performance of the training set was possibly due to the lake's large size and depth relative to the calibration sites or to the limited resolution of the subfossil taxonomy.

Figure 7 Possible scenarios that indicate how nutrient conditions could co-vary with temperature in lakes and potentially affect temperature reconstructions: (a) Gradient of lake productivity (trophic state) in a geographic area with constant and equal temperature. This scenario is suitable for trophic evaluation. (b) The commonly observed positive relation between temperature and lake trophic conditions. The scenario calls for careful interpretation of the results. (c) The ideal situation for building a temperature transfer function. However, such a scheme is rarely observed within a restricted geographical area. (d) For all previous scenarios, the confounding influence of oxygen availability (hypoxia). Reproduced from Velle G, Brodersen KP, Birks HJB, and Willassen E (2010) Midges as quantitative temperature indicator species: Lessons for palaeoecology. *The Holocene* 20: 989–1002.

Approaches that seem to be especially robust when performing paleoenvironmental reconstructions include multisite chironomid-based reconstructions (Larocque and Hall, 2004; Velle et al., 2005), single-site multiproxy reconstructions (see examples given in Brooks, 2003; Nyman et al., 2008; Velle et al., 2010a; see designated sections in the book for other proxies), multiproxy multisite reconstructions (e.g., Heiri et al., 2004), or reconstructions that are validated against instrumental or known environmental records (e.g., Larocque-Tobler et al., 2010). An option including environmental reconstruction by use of more than one proxy seems particularly promising. Such an approach allows the combination of a chironomid-based approach to temperature reconstruction with proxies that have been shown to be sensitive to past temperature change, but remain difficult to use as quantitative temperature indicators on their own during certain periods (e.g., pollen or oxygen isotopes in lake marl). In many combinations, the different paleotemperature proxies would

be affected by past temperature change via fundamentally different mechanisms. A close agreement between different paleotemperature records based on different proxies and from different localities in the same region would therefore increase the confidence that past temperatures rather than other environmental variables were the driving force for the chironomid assemblages. The role of the chironomid-based reconstruction is then to quantify past summer temperature changes, whereas the additional nonchironomid proxies provide independent support for the chironomid-based inferences or point toward problematic parts of the record. For example, Heiri et al. (2004) present a chironomid-based July air temperature reconstruction for the early and mid-Holocene from the Swiss Alps which shows a close agreement with an independently dated pollen-based reconstruction of past tree-line altitude (Figure 8). At present, tree-line altitude in the Alps is largely constrained by temperatures during the growing-season. The close agreement between the chironomid-based July temperature record and the reconstruction of past tree-line altitude from two sites more than 60 km apart suggests that, in this case, the chironomid-based reconstruction successfully captured past centennial-scale changes in summer temperature. In another example, Velle et al. (2010a) used chironomids and pollen from Lake Brurskardet in Norway to infer Holocene July air temperatures. There were incongruences between the inferred temperatures from the two proxies and in the light of the in-lake and catchment-related processes as assessed by diatoms, plant macrofossils and sediment composition, the authors discussed which reconstruction is most likely correct at any one time. The chironomid-inferred temperatures closely resembled results from an ordination analysis of the chironomids during the earliest Holocene. At this time, the pollen suggested unrealistically high temperatures, most likely owing to a high proportion of long-distance transported pollen. The chironomids suggest a Holocene maximum around 9.8 cal ka BP, 800 years prior to the pollen-inferred Holocene maximum. However, according

to the ordination techniques, the chironomid assemblage changed to a limited extent along the main temperature gradient at the time, and to a larger extent along the conductivity gradient. This may suggest that the chironomids responded to changes in conductivity and sediment load. There was coincident substantial shift in sediment input to the lake from inorganic silt to more organic gyttja (Velle et al., 2010a).

In the postglacial period, human impact on lake ecosystems can further complicate the use of chironomids for paleotemperature reconstruction purposes. During the historical period, human land use and industrial activity had led to a widespread eutrophication of lakes in many parts of Europe. Furthermore, prehistoric agriculture and land-use changes may have influenced lacustrine ecosystems as well. Prehistoric anthropogenic effects on lakes were probably not as widespread as lake eutrophication during the historical period. However, evidence suggests that these effects may have been considerable, locally. For example, Heiri and Lotter (2003) present a fossil chironomid record covering the past 9 ka from the Bernese Alps, Switzerland. During three distinct phases, the earliest starting at ca. 4 cal ka BP, the accumulation rate of the dominant lacustrine chironomid taxa was strongly reduced in the record, whereas most running water and littoral taxa showed no changes in accumulation rate. A comparison with other records produced within the framework of a multiproxy study indicated that these decreases in lacustrine chironomids occurred during phases for which geochemical measurements indicate reduced oxygen conditions in the lake. Furthermore, for all three of these phases, paleobotanical proxies showed clear evidence of increased human activity in the lake catchment, such as forest clear-cutting and pasturing. Combined, these records suggest that prehistoric human activity led to anoxic conditions during three distinct periods in the lake's past and reduced the abundance of, or even eliminated, some of the chironomid taxa living in the lake. When a chironomid-temperature transfer function was applied to this record,

Figure 8 Chironomid-inferred temperatures and reconstruction of relative shifts in tree-line altitude from the Swiss Alps. July air temperatures are reconstructed from chironomid assemblages in the sediments of Hinterburgsee, as small subalpine lake in the Northern Swiss Alps. The record is smoothed using a locally weighted regression (LOWESS) smoother. Relative changes in past tree-line altitude were reconstructed based on total tree and *Pinus cembra* pollen in the sediments of Gouille' Rion, a small lake situated at present-day tree-line in the Central Swiss Alps. Data from Heiri O, Tinner W, and Lotter AF (2004) Evidence for cooler European summers during periods of changing melt-water flux to the North Atlantic. *Proceedings of the National Academy of Sciences of the United States of America* 101: 15285–15288.

these episodes were accompanied by distinct coolings in the chironomid-inferred temperatures, and Heiri and Lotter (2003) concluded that these apparent coolings were most likely an artifact of prehistoric human impact on the lake ecosystem rather than a genuine temperature signal.

Future Developments

In recent years, most research on fossil chironomids has focused on their use as paleotemperature proxies. Temperature transfer functions are most easily developed in regions with large temperature gradients in a geographically restricted area. Therefore, most available transfer functions and many of the available postglacial temperature reconstructions in Europe originate from mountainous regions. Considering the ongoing public interest in climate research, and the need for more information on natural climate variability during the pre-instrumental period, it is expected that postglacial chironomid-based temperature reconstruction will continue to remain a focus of research. By optimizing the gradient length for environmental variables other than temperature, chironomids also respond significantly to those variables in modern training sets. Hence, studies are emerging that explore the use of chironomids as quantitative proxies for effective moisture through lake

depth, for example, in Finland (Luoto, 2009), for hypolimnetic oxygen content of the lake, for example, on the Kola peninsula (Ilyashuk et al., 2005), and for TP and chlorophyll *a*, for example, in the United Kingdom (Langdon et al., 2006). As such studies increase in popularity, their resulting paleoenvironmental reconstructions will hopefully be rigorously tested against additional sediment records and against known fluctuations from instrumental records.

Next to methodological advancements, such as the development of new numerical tools for transfer function development (e.g., Velle et al., 2011) and reconstruction validation (Telford and Birks, 2011), and an increase in the taxonomic resolution of fossil chironomid records (e.g., Heiri and Lotter, 2010), one of the main foci will most likely be the expansion of the spatial coverage of chironomid-based temperature records. This may lead to taxonomic harmonization and cross-evaluation of both existing transfer functions and forthcoming temperature reconstructions. In addition, studies that merge our fundamental knowledge of chironomid ecology based on empirical and experimental data with traditional paleolimnological research may provide additional information, for example, when interpreting chironomid stratigraphies, and aid in identifying confounding factors in environmental reconstructions (see Brodersen and Quinlan, 2006 and references therein).

Figure 9 Comparison between stable oxygen isotope records from bulk carbonates (left curve) and from chironomids (right curve). $\delta^{18}\text{O}$ data from the chironomids are per mille relative to the Vienna-Standard Mean Ocean Water (V-SMOW). Gray areas indicate cold periods. GSO, Gerzensee Oscillation; ASO, Aegelsee Oscillation. Reproduced from Verbruggen F, Heiri O, Reichert GJ, and Lotter AF (2010) Chironomid $\delta^{18}\text{O}$ as a proxy for past lake water $\delta^{18}\text{O}$: A Late Glacial record from Rotsee (Switzerland). *Quaternary Science Reviews* 29: 2271–2279.

Chironomid remains are highly resistant to microbial degradation and chemical alteration after their burial in the sediments. Recently, isotopes have been successfully measured on chironomid fossil head capsules to produce records of $\delta^{18}\text{O}$ as an indirect proxy for climatic changes (Verbruggen et al., 2010; Wooller et al., 2004; Figure 9) and $\delta^{13}\text{C}$ to trace dietary links and carbon cycling in the food webs (van Hardenbroek et al., 2010). These methods can potentially provide an alternative to stable isotope measurements on other lacustrine sediment components, such as lake marl and diatoms, and significantly expand the applicability of fossil chironomids as paleoclimatic and paleoecological indicators. There is also great potential to validate paleoenvironmental reconstructions by information gained from isotope studies, for example, to examine how temporal changes in trophic position can influence the reconstructions.

Next to paleoclimate reconstruction, a research field within paleolimnology that has received an increasing amount of attention is the reconstruction of preanthropogenic water quality and ecosystem-baseline conditions for freshwater ecosystems. In Europe, this research has obtained further relevance due to recent developments in European legislation, since the ecological status of lakes and rivers is now defined in relation to the expected state of these ecosystems under minimal anthropogenic influence. Compared with other freshwater indicators such as diatoms, fossil chironomids have received comparatively little attention in reconstructing parameters reflecting past water-quality conditions. However, the examples mentioned above (see Section 'Effects of Pollution on Lake Ecosystems and Reconstruction of Water Quality') indicate that chironomids have potential as quantitative indicators of past nutrient conditions and productivity in lakes. Furthermore, chironomids are one of the few benthic macroinvertebrate groups living in profundal environments that preserve well and remain identifiable in most lacustrine sediments. For restoration purposes, there is therefore considerable potential for using chironomids to reconstruct the natural faunal assemblages in European lakes during the preanthropogenic period and to use them to establish water-quality reference conditions. This potential has been recently demonstrated by the pioneering work of Jyväsjärvi et al. (2010).

Introduction

The use of fossil chironomid remains as indicators of past environmental conditions is now a well established approach (Walker, 2001). From reconstructing trophic status to climate, chironomids have been deemed among the best indicators for their ability to provide quantifiable estimates of change. The use of chironomids in postglacial environmental reconstructions in Australia, New Zealand, and South America has not been extensive, but in recent years has undergone a resurgence of interest with many workers following the success of chironomid-based reconstructions from Europe and North America. A review by Verschuren and Eggermont (2006) provides a detailed account of chironomid paleoecology in the Southern Hemisphere prior to 2006. In this article, we review the published information about postglacial fossil chironomids from Australia, New Zealand, and South America and outline the directions that chironomid research has followed in these areas. We also discuss the importance of chironomid research in the Southern Hemisphere, identifying directions for future research.

Australasian–South American Fossil Chironomid Studies

Australia

Several paleoecological studies that primarily focus on chironomids as paleoindicators have been published from Australia. Paterson and Walker (1974) investigated changes in paleoproductivity. Using the environmental range of tolerance of the chironomid *Tanytarsus barbitarsis*, the authors reconstructed historical salinity changes in Lake Werowrap (38°15'S, 143°30'E) in western Victoria (Figure 1). Based on experiments identifying the range of tolerance of *T. barbitarsis* to total dissolved solids (salinity) and changes in its relative abundance throughout the Lake Werowrap sequence, the authors concluded that freshwater conditions occurred in the early part of the lake's history with a shift to more saline conditions midway through the sequence to the present day. The time span for the Lake Werowrap sequence remains unknown due to the lack of chronology, but it is likely to represent changes since the mid-to late Holocene.

The first study in Australia to provide a quantitative reconstruction of Holocene climate using chironomids was carried out by Dimitriadis and Cranston (2001) from Lake Barrine (17°15'S, 145°38'E), on the Atherton Tablelands, northeast Queensland. This study examined the relationship between the physical and chemical parameters of more than 68 water bodies and their modern chironomid fauna to assess the relative importance of climate and environmental variables on eastern Australian chironomids. They verified a significant

relationship between climate and chironomids, with a correlation (r^2) of 0.94 with mean air temperature of the warmest quarter (TWARM) and 0.59 with mean precipitation of the driest quarter. Through the use of a mutual climatic range method, rather than the more commonly used weighted averaging method, Holocene temperatures were reconstructed for Lake Barrine over the last 9 cal ka. Temperature reconstructions indicate that annual temperatures were warmer by ~2.5 °C from 9.01 to 6.89 cal ka BP but may have been up to 6.6 °C cooler in the summer months between 6.89 and 6.09 cal ka BP. Temperatures remained ~2.5 °C warmer than the current mean from 6.09 cal ka BP to the present day. Precipitation estimates indicate drier climates by ~500 mm of moisture per year from 6.89 to 6.09 and 5.13 to 2.65 cal ka BP, but large ranges associated with these estimates make these reconstructions equivocal. Although estimates of 6.6 °C temperature depressions seem extreme for periods during the Holocene, evidence from regional pollen records provide some support for the chironomid-based estimates and imply similar changes in temperature at these times during the Holocene.

More recently, there have been new developments in Australia using chironomids as quantitative indicators of temperature. Rees et al. (2008) presented a temperature transfer function based on subfossil assemblages of chironomids, Ceratopogonidae (biting midges), and Chaoboridae (phantom midges) from 47 Tasmanian lakes. The chironomid distributions surveyed in this study were strongly influenced by pH, air temperature of the TWARM, annual radiation, Mg^{2+} , precipitation, SiO_2 , and water depth. The observed temperatures were significantly correlated with temperatures predicted from the model, indicating that midges are an appropriate tool for modeling the temperature history of Tasmania. This investigation provides the first such transfer function built for Australia, providing new tools for testing climate hypotheses in the Southern Hemisphere.

Successive studies have focused on chironomid-based environmental reconstructions. The first (Rees and Cwynar, 2010a), shows a temperature reconstruction of the TWARM from two sites Platypus and Eagle Tarn (42°40'S, 146°35'E) in Mount Field National Park, Tasmania. The authors attempt to answer several paleoclimatic questions, including the existence of the Antarctic Cold Reversal (ACR; 14.5–12.5 cal ka BP) in Tasmania, the magnitude of temperature change associated with it, and the temperature differences between the Holocene thermal maximum and modern temperatures. The chironomid records from both sites indicated early warmth with TWARM values at modern levels during the ACR. However, the decrease in the organic content of the loss-on-ignition (LOI) profile from Eagle and Platypus Tarns corresponds with the timing of the ACR in the deuterium content of the EPICA Dome C ice-core. A mid-Holocene thermal maximum, based on the chironomid-inferred temperature estimates, corresponds with

Figure 1 Main regions for postglacial chironomid studies in Australia, New Zealand, and South America.

warming inferred from pollen records in the region. During this period, temperatures were considered to be similar to or 1.5 °C warmer than modern. In a second study, [Rees and Cwynar \(2010b\)](#) investigated the response of chironomids to a pH gradient in Tasmania. The inference model suggests that higher species richness at low pH may result from the large pool of tropical taxa that have adapted to naturally occurring acidic conditions. The authors suggest that during glacial episodes an isthmus would have formed between mainland Australia and Tasmania, allowing for the migration of plants and animals. This could have been a potential route of colonization for the suite of acid-adapted taxa from mainland Australia and Southeast Asia into Tasmania. This model is among the few that have been developed to estimate pH from chironomid remains.

New Zealand

The first paleoecological studies involving chironomids from New Zealand have primarily been qualitative investigations focusing on paleolimnological changes such as lake productivity or catchment and lake system development. Early work was carried out by [Deevey \(1955\)](#) from a swamp deposit sequence in the upper Pyramid Valley (42°58' S, 172°35' E), central South Island. In this study, [Deevey \(1955\)](#) used a range of terrestrial and aquatic macrofossils including cladocera, ostracods, mollusks, plant macrofossils, charophytes, green algae, pollen, diatoms, and chironomids to reconstruct lake history. The dynamics of these proxies were interpreted to indicate trophic changes and lake-level fluctuations during the past ca. 3.9 cal ka BP. Interpretations from this study are generalized, mainly due to a poor taxonomic resolution and ecological understanding of New Zealand freshwater biota at the time.

In two other studies, [Schakau \(1986, 1990\)](#) examined chironomids from Holocene sequences in two lakes: Lakes Taylor (42°46' S, 172°14' E) and Grasmere (43°59' S, 171°45' E), both located in the central South Island of New Zealand. In Lake Taylor ([Schakau, 1986](#)), the chironomid assemblages spanning the last ca. 3.2 cal ka indicated a higher abundance of Tanytarsini in the older sediments and a shift in dominance from Tanytarsini to Chironomini after ca. 2.5 cal ka BP. This shift was not statistically significant and therefore not considered to be a response to climate change or lake trophic status.

At Lake Grasmere ([Schakau, 1990](#)), changes in chironomid assemblages were used to reconstruct lake paleoenvironmental history over the last 6.8 cal ka. The sequence is dominated by *Corynocera* sp. but shows marked shifts in faunal abundance and composition, characterized by increases in Chironomini, Orthocladinae, and Tanytarsini genera. The observed changes were not interpreted to be driven by climate as pollen analysis from the site did not indicate any major vegetation changes that might be driven by climate change during this time. The dominance of *Corynocera* sp. and the relatively stable faunal assemblage suggest a period of general environmental stability over the past 6.8 ka. Distinct changes in chironomid structure throughout this time were thought to reflect short-term changes in lake productivity, hydrological inflow, and rate and type of sedimentation.

More recently, [Woodward and Shulmeister \(2005\)](#) combine pollen, Trichoptera, chironomids, and algal abundance to reconstruct the development of coastal Lake Forsyth (43°48' S, 172°44' E), South Island, from a tidal bay to a barrier-dammed lake. The main fluctuations recorded in chironomids (mainly *Chironomus* sp.) and other aquatic taxa during this time were interpreted as a response to changes in salinity, catchment deforestation, and eutrophication throughout the past 7 cal ka. This study indicates a significant relationship between the abundance of aquatic taxa and regional vegetation, and proposes catchment deforestation resulting from human disturbance as the main cause of biological change in the lake history. Increases in abundance and diversity of chironomids after AD 1840 suggested an increase in sediment and nutrient input into the lake and a decrease in salinity as a result of deforestation. In the late 1800s, a significant peak in freshwater algae and a drop in abundance and diversity of chironomids and other aquatic invertebrates were interpreted as a period of lake eutrophication. This study emphasizes the advantages of using multiproxy analyses to interpret environmental change.

Since these initial studies, there have been major improvements both in the statistical approaches and the subfossil taxonomic identification applied to New Zealand chironomids, culminating in the development of several chironomid-temperature inference models ([Dieffenbacher-Krall et al., 2007; Vandergoes et al., 2008; Woodward and Shulmeister, 2006a,b, 2007](#)). The first chironomid-based transfer function

developed in the Southern Hemisphere was published recently by Woodward and Shulmeister (2006a,b). They analyzed chironomids and environmental variables from 46 New Zealand lakes, identifying temperature (February mean air temperature) and lake productivity (chlorophyll *a*) as the main drivers of chironomid distribution. The temperature model was more robust with an r^2 (jack) of 0.77 and a prediction error (root mean squared error of prediction, RMSEP jack) of 1.31. A less reliable model was produced for chlorophyll *a* with a correlation r^2 (jack) of 0.49 and a prediction error (RMSEP jack) of 0.46 Log¹⁰ mg l. In this paper, the authors identify the problematic distribution of the ubiquitous *Chironomus* morphotype.

More recently, Dieffenbacher-Krall et al. (2007) provided a crucial cornerstone for the development of modern chironomid–temperature calibration sets and the use of chironomids to quantify postglacial climatic change in New Zealand. The study used data from 61 lakes and included a number of lakes from high altitudes in South Island, New Zealand. The multivariate analysis showed that summer air temperature (SmT) explains the greatest amount of variance in chironomid distribution of any of the measured variables. This investigation presents a robust inference model (RMSEP jack of 1.27 °C, r^2 jack 0.80) to reconstruct mean SmTs from subfossil chironomids. Soon after, Vandergoes et al. (2008) applied the Dieffenbacher-Krall et al. (2007) chironomid-inferred temperature model to a down-core chironomid study of Boundary Stream Tarn (44°02'S, 170°07'E) in the Southern Alps, New Zealand (Figure 2(a)). In this study, pollen and chironomids were compared and the chironomid model was used to quantify Late Glacial climate change and explore the existence of cooling associated with the ACR. The results indicate a ca.1000-year disruption to the Late Glacial warming trend and an overall cooling consistent with the ACR. The main interval of chironomid-inferred summer temperature depression (2–3 °C), indicated by increases in cool climate *Chironomus* and *Tanytarsus* sp., lasted about 700 years during the ACR. Following this cooling event, both proxies indicate a warming step to temperatures slightly cooler than present during the Younger Dryas (YD) chronozone (12.9–11.5 cal ka BP; Figure 2(b)). Minor differences between the two proxies were attributed to seasonal climate variations and a possible lag in vegetation response to abrupt climate

change. The chironomid–temperature reconstruction at this site represents the first of its kind for the Late Glacial in New Zealand, and provides a quantitative assessment of climate change for the period associated with the ACR.

South America

Pioneer chironomid work has been carried out in the Neotropics and three studies dealing with fossil midges have been published. Goulden (1966a,b) studied fossil midges from Laguna de Petenxil and another pond in Guatemala. Interpretations from both studies are vague, mainly due to the low abundance and poor preservation of the remains and the lack of an accurate chronology. In Venezuela, Binford (1982) carried out a paleolimnological investigation in Lake Valencia using animal remains and some chemical and physical variables to reconstruct the last 12.5 ka of lake history. Results of this work indicate that lake-level fluctuations and trophic changes occurred during the time span of the core. More recently, fossil chironomid investigations have been conducted in the southern Andes of Argentina and Chile (Ariztegui et al., 1997; Bianchi et al., 1997, 2000; Corley and Massafiero, 1998; Massafiero, 2000; Massafiero and Brooks, 2002; Massafiero and Corley, 1998; Massafiero et al., 2004, 2005, 2008, 2009). These studies were concentrated in two areas: in Northern Patagonia, Argentina, within the limits of the Nahuel Huapi National Park (41°S) and in Southern Chile on the Peninsula de Taitao and the Chonos Archipelago (46°S). Here, we review the main focus of these publications: paleoclimate, and paleo-productivity reconstructions.

Paleoclimatic reconstructions

Studies focusing mainly on Late Glacial climate reconstructions address evidence of Late Glacial Northern Hemisphere climate signals (i.e., YD cooling) in South America. To date, results of investigations at four sites using fossil chironomids to reconstruct past climate during the Late Glacial period in Argentinean and Chilean Patagonia have been published. In Ariztegui et al. (1997), changes in pollen, fossil chironomids, and geochemistry during the last 15 cal ka BP at Lake Mascardi (41°20'S, 71°34'W; Figure 3) were interpreted as a response to a climate cooling coincident with the timing of the YD

Figure 2 (a) Location of Boundary Stream Tarn, a kettle lake within lateral moraines of the Lake Pukaki Last Glacial Maximum ice advances. Aoraki (Mount Cook) in the background. (b) Late Glacial cooling expressed in pollen and chironomid proxies at Boundary Stream Tarn. Main period of cooling in both proxies coincides with the timing of the ACR and is 2–3 °C below modern (13.4 °C).

Figure 3 Eastern end of Lago Mascardi (800 m a.s.l., 30 km² surface area, 200 m water depth) located ~15 km from the Mt Tronador ice cap that feeds the lake. Glacial ice from Mt Tronador filled this valley during the Last Glacial Maximum. The fossil core site is located outside the photograph.

Northern Hemisphere cold event. Results showed that between 13.47 and 11.96 cal ka BP, there was a decrease in the total pollen influx as a consequence of an increase in inorganic sedimentation followed by a sharp decrease in the hydrogen index. These results were interpreted as a response to cooling accompanied by an increase in subglacial erosion due to an advance of the Tronador ice cap that feeds the proglacial lake. The disappearance of the warm-adapted *Chironomus* and the decline in the total chironomid abundance at this time also suggested a climatic deterioration.

In a multiproxy paleolimnological study carried out in Lake El Trebol (41°04'9"S, 71°30'9"W), Bianchi et al. (1997) analyzed fossil chironomids, pollen, and geochemistry to reconstruct paleoenvironmental history. Changes in these proxies were interpreted to indicate climatic fluctuations during the last 14 cal ka BP. The increase of fossil midges, organic matter, biogenic silica, and nutrients from ca. 12.42 cal ka BP was interpreted as a change in lake productivity due to climatic amelioration. Subsequently, Bianchi et al. (1997) combined pollen, chironomids, rare earth elements, heavy metals, and fossil pigments to show the postglacial evolution of the landscape and biota in the area surrounding Lake El Trebol, providing the basis for future accurate paleoenvironmental reconstructions. Based on changes in the analyzed proxies, three different periods were recognized: the Late Glacial, a transition, and the Holocene period. Chironomids showed a gradual replacement of littoral Orthocladinae fauna, abundant in the transition zone, by profundal Tanytarsini taxa, present in the Holocene, indicating more autochthonous lake production. Changes in pollen and paleopigments were consistent with changes in midge assemblages. These results suggested a climatic amelioration during the Late Glacial/Holocene transition. Climate interpretations were consistent with those observed at Lake Mascardi (Ariztegui et al., 1997). Chironomid assemblages and biogeochemical parameters also indicated changes in lake productivity during Holocene times. Nevertheless, the interpretation of climate changes in both

investigations remained speculative due to the lack of resolution and a precise chronology.

The first high-resolution late Quaternary environmental reconstruction using chironomids in South America was published by Massafiero and Brooks (2002). Changes in the chironomid assemblages at Laguna Stibnite (46°25'S, 74°24'W) in the Taitao Peninsula in Chile suggested that the climate in southern Chile was drier and at its coolest during the YD chronozone. Between ca. 13 and 11.2 cal ka BP, the cold-stenothermic Podonominae were consistently present in every sample, reaching a peak abundance during this period. This suggests that lake waters were cool and oligotrophic during the YD. The low concentration of head capsules also reflects low lake productivity. The dynamics of the late Quaternary chironomid fauna of Lake Stibnite shows a remarkably cyclical pattern, which was interpreted as being linked to changes in precipitation. During the Holocene, the presence of a *Limmophyes/Chironomus/Phaenopsectra/Parachironomus* assemblage between 10.6 and 7.2 cal ka BP and 2.5 and 1.5 cal ka BP suggested dry periods with low lake levels. Within a regional context, results from beetles from Puerto Edén (Ashworth et al., 1991) located 300 km south of Taitao Peninsula also suggested changes in precipitation during the Holocene, although they were almost out-of-phase to those inferred at Laguna Stibnite. If these interpretations are both correct, changes in precipitation patterns may be a consequence of latitudinal shifts of the Westerlies (Massafiero and Brooks, 2002). However, the climatic interpretation that suggested cooling during the YD is not in agreement with other investigations carried out in the lake. Pollen records from Lake Stibnite (McCulloch et al., 2000) and other lakes in this region of Chile show no evidence of cooling during the Late Glacial period (e.g., Haberle and Bennet, 2004). In contrast, other sites in Patagonia show changes in pollen assemblages at the end of the Late Glacial that have been interpreted as a response to climatic cooling (e.g., Heusser et al., 1996; Moreno, 1997). The inconsistencies between these interpretations have contributed to the ongoing controversy concerning the presence of a YD cooling in South America.

Massafiero et al. (2005) carried out a study on pollen and fossil chironomids in Laguna Facil (44°19'S, 74°17'W), located in the Chonos Archipelago in Chile. In this article, the authors argue that chironomids respond to local rather than regional environmental changes. Chironomid stratigraphical changes coincided closely but not synchronously with changes in the pollen and charcoal. The lag in the response of midges compared with the forest trees would suggest that the midge fauna responds to changes brought about by the migration and colonization of these trees in the lake catchment. This could be in response to changes in the structure of the forest canopy and amount of tree shade close to the shores of the lake, or to changes in water chemistry brought about by soil development. However, a change in the chironomid assemblage at ca. 7.2 cal ka BP, preceding the resurgence of *Pilgerodendron*, suggests a midge response to regional climatic change.

Despite the faunal similarities and the close proximity of Lake Facil to Lake Stibnite, no response to a cooling event coinciding with the YD was recorded in the chironomid assemblages from Lake Facil. The explanation for this (Massafiero et al., 2005) pointed to the more northerly location of Lake Facil than Laguna Stibnite, which is less likely to

have been influenced by any resurgence of Andean glaciers during the YD. Geographic variability in glacial activity would indicate that climatic conditions were possibly insufficiently intense and/or of insufficient duration to uniformly affect regional paleobiotic changes; therefore, a response during the YD may be recognizable at some sites but not at others.

Recently, [Massaferro et al. \(2009\)](#) combined pollen and fossil chironomid records from the Huelmo site, Chile ($41^{\circ}31'S$, $73^{\circ}00'W$) to elucidate the timing and structure of climate changes during the final portion of the Last Glacial Maximum and during the last glacial termination (LGT) in NW Patagonia. During the Late Glacial/Holocene transition, chironomid assemblages show cooling pulses at 14 and 13.5 cal ka BP ([Figure 4](#)). The first cooling was interpreted as a low-magnitude precursor event, contemporaneous with the ACR, giving support for the Huelmo Mascardi Cold Reversal (HMCR; [Hajdas et al., 2003](#)). This study provides one of the first detailed chironomid and pollen records in the Southern Hemisphere spanning the culmination of the Last Glacial Maximum through the LGT and into the Holocene. The results reported in this paper clearly demonstrate the sensitivity of fossil chironomids to temperature and moisture fluctuations during the last transition from glacial maximum to interglacial conditions in NW Patagonia.

Paleoproductivity reconstructions

A number of studies from South America focus on the relationships between chironomids and lake productivity. [Massaferro and Corley \(1998\)](#) studied the chironomid paleodiversity from Lake Mascardi. The study demonstrates how major environmental episodes such as volcanic eruptions, climatic cooling/warming, and changes in lake level occurring during the Late Glacial period affected midge diversity patterns. The authors suggest that long-term studies reconstructing the history of lake diversity provide important information for present-day conservation management. In conjunction with this study, [Corley and Massaferro \(1998\)](#) published the first fossil insect community dynamics study in Patagonia. Using a long-term apparent turnover rate, the authors show chironomid community

extinction/immigration patterns along a 10 m sediment core representing 15 ka of lake history. This kind of work is important from an ecological perspective to facilitate the interpretation of current trends in diversity and succession patterns. Subsequently, [Massaferro \(2000\)](#) published the complete chironomid assemblage from Lake Mascardi, covering the last 15 ka BP. In this study, changes in chironomid species abundance are compared to diversity indices and also to changes in total organic carbon. Sampling resolution was not sufficiently high to discern short-term chironomid responses to environmental change; however, changes in midge assemblages were interpreted to be related to temperature and also to changes in lake productivity. [Massaferro et al. \(2004\)](#) studied geochemical and chironomid records from a short core from Lake Morenito ($41^{\circ}39'S$, $71^{\circ}31'W$), located near the city of San Carlos de Bariloche in Patagonia. Due to the expansion of the population in recent years, Lake Morenito and surrounding areas have experienced moderate human impact such as the deforestation, fish introduction, and building construction. This work shows the response of chironomids and geochemistry to natural and anthropogenic (European) environmental disturbances during the last 200 years. The main fluctuations recorded in chironomid assemblages during the time span of the core were interpreted as a response to human disturbances in the catchment area, demonstrating the value of chironomids in reconstructing paleoproductivity. It also demonstrates the utility of combining multiple proxies (chironomids, tephra and sediment analysis, organic matter, and chronology) in the interpretation of such changes.

Hemispheric and Interhemispheric Comparison

Although more high-resolution paleotemperature studies are warranted for the Southern Hemisphere, some tentative comparisons with other regions of the globe can be made from those that have already addressed the Late Glacial–interglacial climate change in the mid-latitudes of the Southern Hemisphere. This topic has been extremely controversial in the

Figure 4 Key pollen indicator taxa and cold-tolerant chironomid taxa from the Huelmo site. The Huelmo Mascardi Cold Reversal encompasses zones 3c and 4.

past, with some paleoclimate records indicating changes that are more coincident with cooling noted in Antarctic ice-core records, that is, the ACR, than with cooling noted from the North Atlantic region (associated with the YD chronozone). Other records have suggested gradual warming with no reversals in the Southern Hemisphere. Studies from lacustrine environments of New Zealand, Tasmania, and South America can help resolve this debate. Chironomid records from Tasmania do not provide clear evidence of an ACR or YD cooling during the Late Glacial while in New Zealand there seems to be clearer evidence of a 2–3 °C cooling during the time of the ACR. Chironomid records suggest that a distinct climatic reversal similar to the YD cool phase of the North Atlantic region occurred in sites from Central Chile and Argentina. This mid-latitude cooling was recently identified as the HMCR (Hajdas et al., 2003). Nevertheless, chironomid assemblages also indicate that a cooling trend started earlier than the HMCR, at ca. 14.4 cal ka BP. This cooling corresponds with the timing of the ACR (Massaferro et al., 2009). Comparison of chironomid results with both EPICA Antarctica and GISP2 Greenland ice-core records indicates similar Late Glacial climatic events, but their full interpretation awaits the development of a robust inference model (South America) and the development of more fossil chironomid records from sites across the Southern Hemisphere.

From this review it is clear that much progress have been made in the Australasian region in the use of chironomids as quantitative indicators of past conditions. Major achievements have occurred in New Zealand (Dieffenbacher-Krall et al., 2007; Vandergoes et al., 2008; Woodward and Shulmeister, 2006a,b, 2007) and Tasmania (Rees et al., 2008, Rees and Cwynar, 2010a,b). Identification keys for the modern chironomid fauna continue to be developed or New Zealand (Boothroyd, personal communication), and for the subfossil remains of New Zealand (Dieffenbacher-Krall et al., 2008 online), Tasmania (Cwynar and Rees, personal communication), and South America (Massaferro, personal communication).

Future Research Directions

The fact that chironomids have the potential to provide detailed paleotemperature reconstructions is extremely important in the Southern Hemisphere where quantitative estimates of temperature change are limited. Combined with other proxies including pollen, diatoms, and isotopic measurements, chironomids can contribute substantially to multiproxy environmental reconstructions to produce more robust estimates of climate change. They can also be used to calibrate regional paleotemperature estimates derived from nonecological indicators such as snowline reconstructions and ice cores. The importance of attaining quantitative temperature estimates from landmasses within the Southern Hemisphere is critical to clarify climate relationships between the Northern and Southern Hemispheres, and therefore identify possible coupling mechanisms. Much progress has been made in the study of fossil midges from the Southern Hemisphere; however, further work is required in two main areas: chironomid taxonomy and ecology and quantitative models.

Modern Taxonomy and Ecology

Early studies by Edwards (1931) and Brundin (1966) were the first to recognize a circum-Antarctic chironomid faunal connection and make significant contributions to the knowledge of Southern Hemisphere chironomid taxonomy and biogeography. Since then, other researchers from New Zealand (e.g., Boothroyd, 2002; Forsyth, 1971; Sublette and Wirth, 1980) and South America (e.g., Andersen and Contreras-Ramos, 1999; Cranston, 2000b; Fitkau and Reiss, 1973; Paggi, 1998) have made notable advances in furthering our knowledge of the taxonomy and distribution of Southern Hemisphere chironomids, while work by Cranston (2000a) has made an exceptional contribution to the identification and ecology of the Australian chironomid larval fauna. Even with these recent advances, knowledge of chironomid taxonomy of Australia, New Zealand, and South America remains limited. The number of species currently documented is considered conservative and many taxa remain undescribed (Boothroyd, personal communication; Cranston, 2000b). A further problem is that the existing taxonomic descriptions are based on characters found in adults or pupae, while the taxonomy of the larval stages has largely been ignored. As a consequence, in New Zealand and South America, many of the existing taxa can only be identified to the generic level (Figure 5) and identification keys for the larval stages of chironomids in these regions are scarce. Many chironomid taxa remain undescribed because of a lack of ecological investigations. The result is that the knowledge of ecological requirements, tolerances, and species distribution of these insects in Australia, New Zealand, and South America is incomplete. These factors hamper our understanding of the causes of change in modern chironomid assemblages and inhibit the use of fossil chironomid assemblages, which relies solely on the identification of subfossil larval head capsules for environmental reconstructions. There is a need for the improvement of taxonomic resolution of modern and subfossil chironomids. In the Southern Hemisphere, there is just one key for the identification of the chironomid fauna from Australia (Cranston, 2000a), but similar keys have yet to be published for New Zealand or South America. For the first time, Massaferro and Brooks (2002) described specimens of the subfossil chironomid fauna from a Chilean lake and identified additional taxonomic groups that could be ecologically related to the European taxa. However, more taxonomic and ecological work is needed in the Southern Hemisphere, especially regarding the distribution and habitat requirements of chironomids. A standardized taxonomic approach, together with an improvement in taxonomic resolution, will allow direct comparisons between chironomid investigations from Australia, New Zealand, South America, and Africa, providing an invaluable tool for biogeographical and paleolimnological research.

Chironomid–Temperature Inference Models

Quantitative estimates of paleotemperature can only be achieved through the development of chironomid–temperature inference models specific to the geographic region of the

Figure 5 Head capsule remains of South American *Tanytarsus* sp. yet to be classified below generic level. Distinction of subgroups based on the differing characteristics of the spur on the antenna pedestal (arrows). Photographs by J. Massafiero.

paleoclimate analysis. In the Northern Hemisphere, a number of studies have used the training set approach to determine how environmental variables, including summer temperature, are important in determining chironomid community composition. The recent development of inference models from Tasmania (Rees et al., 2008; Rees and Cwynar, 2010a,b), New Zealand (Dieffenbacher-Krall et al., 2007; Woodward and Shulmeister, 2006a,b) represents a significant advance in the use of chironomids as paleoenvironmental indicators. However, improvements to this initial calibration data set, including a more refined taxonomy and the addition of more lakes evenly distributed along a wider temperature gradient, are needed to improve the performance of these models. At present, the lack of chironomid–temperature inference models from South America is a serious impediment in providing robust, quantifiable estimates of temperature from existing Late Glacial and Holocene chironomid records. Progress in this area is underway and Massafiero (2010) presented the results of a training set of 60 chironomid taxa, 6 environmental variables and 102 lakes from Patagonia (Argentina and Chile) located along a transect from 40 to 54° S from southern South America. Multivariate analysis indicates that temperature (December/January mean air temperature) and mean annual precipitation explains the greatest amount of variance in chironomid distribution of any of the measured variables. However, the influence of low head capsule abundance in ultraoligotrophic lakes from Patagonia currently limits the performance of the transfer functions and work is currently underway to refine these models.

Introduction

The advent of atmospheric cosmogenic radiocarbon dating by Libby in the 1950s brought high precision ages of important

geological and archaeological events and solutions to long-standing marine and terrestrial Quaternary problems. Over the next three decades, methods were developed that could measure cosmogenic isotopes in minerals at the precision

necessary for surface exposure dating. However, since the mid-1980s, there has been a comparable revolution in Quaternary science due to applications of terrestrial cosmogenic nuclides (TCN) produced *in situ*. Many previously intractable geochronology questions are being addressed, many new questions are being asked, and there has been an explosion of ideas related to rates of surface processes.

Synthesis of TCN applications

Recent reviews of applications of TCN methods are provided by Bierman and Nichols (2004), Cockburn and Summerfield (2004), T. J. Dunai (2010), Gosse and Phillips (2001), Muzikar et al. (2003), and Niedermann (2002). To date, TCN methods comprise six routinely-utilized isotope-mineral systems: ^3He , ^{21}Ne , ^{10}Be , ^{26}Al , ^{36}Cl , and ^{14}C . The former two are stable noble gases and the latter four are listed in order of decreasing half lives – 1.5 Ma (currently debated), 0.7 Ma, 0.3 Ma, and 5.7 ka. Some TCNs are calibrated for specific minerals due to:

- (1) diffusion constraints (e.g., ^3He diffuses too quickly from quartz to make it useful as a geochronology tool, but is retained in minerals such as pyroxenes and olivine);
- (2) production rates (^{36}Cl cannot be produced in pure quartz); and
- (3) other issues, such as high native concentrations of the isotope or its comparative isotope for AMS measurement (for instance, measurements of ^{26}Al in an aluminosilicate are difficult).

So far, one isotope has been calibrated for measurement in whole rock samples (^{36}Cl), so virtually any rock type can be used for TCN research. The stability of the noble gases permits the measurements of the oldest surfaces on Earth (tens of millions of years). An advantage of the radionuclides is that their concentration is dependent on decay rate as well as exposure duration, offering an extra degree of freedom for calculating long exposure durations or avoiding difficulties associated with inheritance. For instance, the rapid decay of ^{14}C offers a useful geochronology tool to date glaciated surfaces (or sediment derived from them) that have not been deeply eroded. Those surfaces would retain some TCN concentration from exposure prior to ice cover. However, if the ice cover was of sufficient duration (say 40 ka), most of the ^{14}C would be decayed and its concentration measured today would reflect the timing of exposure since the surface was uncovered. The youngest and still experimental member of the TCN toolbox is the noble gas ^{38}Ar . However, other new isotope and mineral systems are being developed to provide more applications (see **Methods**).

Every TCN experiment depends on the past century (Gosse and Phillips, 2001) of efforts of theoretical and experimental physics, analytical chemistry, geochemistry, geomorphology, and geophysics. Sample selection must consider geometry effects and the angular dependence of cosmic radiation. Sample preparation requires planning to ensure the proper isotope-mineral system is selected based on lithology and mineral abundance. To achieve the desired precision, the analytical limits of the isotope mass spectrometry, exposure duration, site production rate and sample depth, mass of sample,

number of samples per site, abundance of non-cosmogenic species of the same isotope, and complexity of exposure history, must all be considered. The analyses of these nuclides require high precision atomic-grade noble gas mass spectrometers or accelerator mass spectrometers.

Besides physical improvements to both of these systems, spectrometry methods and target preparation procedures have improved significantly over the past decade (both techniques routinely analyze TCN samples with 2 to 4% 1σ precision). Finally, when a TCN method is applied, numerous calculations and sensitivity assessments are required before interpreting the concentration as an age or an erosion rate. Cosmic ray physics and empirical measurements must be relied upon to scale production rates from sea level high latitude to the sample site. Decisions must be made regarding which production rate to use, and whether to compensate for geomagnetic field effects, snow cover, bulk density variations with time, and other factors. The intensity of sample specific calculations and analyses is a significant departure from most Quaternary dating methods, which often only require a thorough consideration of stratigraphic context before the data can be used.

A major premise of all TCN methods is that the nuclides are produced at known rates. Production of cosmogenic isotopes in minerals exposed to secondary radiation depends on the nuclide and mineral system and other environmental factors. Secondary radiation is produced when primary galactic cosmic rays (primarily fast protons) interact with nuclei in the Earth's atmosphere or within the upper few meters of the lithosphere. TCN production rates vary spatially as a function of geomagnetic field effects (dipolar and non-dipolar), and atmospheric depth. TCN production also varies temporally, in a way similar to atmospheric radiocarbon production variation under stronger or weaker magnetic field intensities. Additionally, the concentration of TCNs in rock depends on erosion, movement, or burial of the surface. Production rates for most locations are probably known to within 15% at the 1σ confidence level. However, the uncertainty is not well defined due to the number of variables involved and the difficulty in establishing a highly accurate production rate for a given time and place. The principal objective of two concurrent major international research programs, CRONUS-Earth in North America and CRONUS-EU in Europe, was to improve knowledge of TCN production rates. Results from these studies are in the process of publication, however, results from the intercomparison of different sites in the CRONUS program indicates that the level of uncertainty in production rates can be reduced to a few percent for ^{10}Be , but substantial challenges remain for other radionuclides.

TCN methods can be used to directly date rock or sediment landforms. By 2006, hundreds of lava flows and thousands of boulders on moraines have been dated directly with TCN measurements. Exposure of surfaces in hyper-arid regions, such as the Antarctic dry valleys and the Atacama Desert (Dunai et al., 2005) record exposure histories since the Pliocene and Miocene. The upper time range of the method is limited by surface stability although for long (hundred million years) exposures, changes in the diffusion of the noble gases and the production of non-cosmogenic species can become the limiting factors.

Secondary cosmic radiation (primarily fast, epithermal, and thermal neutrons and muons) is attenuated with depth below the surface at a rate dependent on the particle attributes (type, charge, energy) and the bulk density of the rock or sediment. Production of TCN isotopes is routinely detected at depths exceeding 5 m. The attenuation of the cosmic ray secondaries with mass has many useful implications. For instance, the differences in the decrease in total production rate of ^3He and ^{38}Ar with atmospheric depth may lead to future uses of their ratio for paleo-altimetry (surface uplift) measurements. Furthermore, the predictable decrease in concentration with depth creates an important advantage for TCN over other geochronology methods. Because the concentration is sensitive to depth, the method can be used to determine directly the rate and style of erosion of landforms and landscapes. A third implication of the penetration of cosmic rays through mass is that the definition of 'surface' can include surface evolution, so that it is possible to yield a minimum exposure age on an eroding surface, although the original surface may have been changed or completely stripped.

TCN exposure methods have already made lasting impacts on society and science outside Quaternary geology. For instance, Partridge et al. (2003) have provided $^{26}\text{Al}/^{10}\text{Be}$ burial ages on sediment at Sterkfontein, South Africa, showing that associated hominid fossils were deposited in the Lower Pliocene. The capacity to date surfaces with millions of years of exposure has provided an important extension of the billion-to million-year timescale of rock exhumation history derived from high- and low-temperature thermochronology methods, such as apatite (U-Th)/He.

CRONUS Calculator

An important development as a result of the many studies conducted over the last decade has been the development of a calculator for cosmogenic nuclide studies, so that standardized computations of exposure age and erosion rates can be estimated for ^{10}Be and ^{26}Al measurements (Balco et al. 2008). This calculator can be found at the web address hess.ess.washington.edu.

Preface

The purpose of the following four articles is to provide a review of the current state of knowledge concerning:

- (1) the theory of cosmic ray interactions with minerals;
- (2) recent developments in production systematics and analytical and geochemical methodologies;
- (3) applications of the technique for geochronology; and

- (4) applications of the technique for landscape evolution studies.

Lal (see [Cosmic Ray Interactions in Minerals](#)) provides a systematic review of the important interactions that produce TCN. The article describes the origin, composition, and energy spectra of cosmic rays, and their fate from origin to Earth's surface. Lal provides a summary of the founding physics theory and experimentation upon which the TCN technique is based, and discusses some of the shortcomings of knowledge that remain as important sources of systematic error in the methods. Schaefer and Lifton (see [Methods](#)) provide a thorough review of the recent progress that has been made in TCN production systematics and the iso- topic procedures. They highlight one of many exciting strategies undertaken by the international CRONUS initiative to improve TCN techniques. Ivy-Ochs and Kober (see [Exposure Geochronology](#)) summarize a wide range of applications of TCN methods for dating surfaces and events, and include caveats and limitations to different approaches. Granger (see [Landscape Evolution](#)) demonstrates how the TCN methods offer more than geochronology, because their concentrations can be interpreted directly as erosion rates and burial histories to provide insights into landscape evolution that could otherwise not be resolved.

Introduction

During the last 10–15 years, some 50 years after their initial discovery (Schaeffer and Davis, 1956), terrestrial cosmogenic nuclide (TCN) applications have had a revolutionary impact on various Earth science disciplines including Quaternary geology, geomorphology, sedimentology, volcanology, and paleoclimatology. The rapid progress has been fueled by recent methodological developments in TCN science, creating a quantitative foundation for studying a broad range of sedimentary processes on the Earth's surface. Simultaneously, it has become clear that the production systematics of TCNs on Earth are complex and are influenced by many parameters, known to varying degrees, all of which need to be taken into account for accurate interpretations in TCN applications. TCN research at the beginning of the twenty-first century is driven by the enormous potential of this tool in a rapidly growing number of applications in Earth science and beyond, but at the same time the effects of numerous uncertainties must be considered to avoid overinterpretation of TCN measurements.

A primary application of TCNs is the field of surface exposure dating (SED). The basic principle of SED is simple: secondary cosmic rays (mostly high-energy neutrons) interact with target atoms in rocks and sediments on the Earth's surface, producing cosmogenic nuclides *in situ* (dominantly via spallation reactions). Several of these *in situ* cosmogenic nuclides can be measured in excess of the natural background. If the rate of production per unit time is known, if the exposure of the surface has been continuous, and if the surface to be sampled has not been eroded, the measured cosmogenic nuclide concentrations can be directly translated into an exposure age. In nature, the application of TCNs is more complex because of the uncertainties in the quantitative knowledge of production rates and because of several natural processes modifying the surface with time (e.g., erosion) or interrupting the exposure (e.g., sediment/snow cover).

There are various recent review articles summarizing SED methods. The comprehensive paper by Gosse and Phillips (2001) presented the first complete overview of TCN science including overall uncertainty discussions. More recent reviews were provided by Blard et al. (2006) and Ivy-Ochs and Kober (2010). Balco (2011) reviews the potential of SED on glacial chronology. Niedermann (2002) reviews in detail the cosmogenic noble gas method and presents an overview of modern applications. The reviews by Cerling and Craig (1994), Kurz and Brook (1994), and Lal (1991) are already introductory classics, presenting the basic principles of the method and outlining the immense potential of the SED method. The rapid progress in the cosmogenic dating field is arguably best reflected in the breadth and depth of innovation reported since these classic reviews. Many of these advances have resulted both directly and indirectly from a major international

collaborative effort from 2004 to 2011 to better define the systematics of TCN production – the Cosmic-Ray Produced Nuclide Systematics on Earth (CRONUS-Earth, www.physics.purdue.edu/cronus) project, and its sister project from Europe (CRONUS-EU, www.cronus-eu.net/). This very recent progress is the focus of this short article. The new findings are presented and discussed in two different sections, namely, nuclide-specific news and production-rate novelties.

TCN-Specific Progress

One of the major areas of recent progress is the increase in sensitivity of cosmogenic nuclide methods, including extension of the exposure age timescale into the historical period, and the broadening of the target minerals that can be used for SED. The recent developments for each TCN are briefly discussed below.

High-Sensitivity ^{10}Be Analysis from Quartz

In situ ^{10}Be produced in quartz has become the workhorse of SED in the last several years, evidenced by a dramatic increase in published ^{10}Be studies. A few recent studies introduced progress in ^{10}Be SED by dating historical moraines as young as a few hundred years and resolving up to five individual glacier culminations during the last millennium, making the case for centennial resolution (Licciardi et al., 2009; Schaefer et al., 2009; Stone et al., 2003b). The internal consistency of ^{10}Be ages of boulders from one moraine also shows that the problem of inherited nuclides in SED samples can be close to zero in some cases (Figure 1).

^3He from Olivine, Pyroxene, Fe/Ti-Oxide Minerals, and Garnet

^3He is a TCN that is widely used as a result of the well-calibrated production rate (Goehring et al., 2010; Niedermann, 2002) and the wide applicable time range from 1 ka (e.g., Gayer et al., 2004) to more than 10 My (Schäfer et al., 1999). Most studies assume 100% spallation from high-energy nucleons as the production pathway for cosmogenic noble gases (i.e., assuming muogenic and thermal neutron production to be negligible). Cosmogenic helium is routinely analyzed from pyroxene and olivine (e.g., Kurz, 1986; Licciardi et al., 2001). Some success in measuring cosmogenic helium from quartz was reported early from cold and dry Antarctica (Brook and Kurz, 1993), but most studies since have found that quartz does not quantitatively retain cosmogenic ^3He (Niedermann, 2002 and references therein). One of the challenges is to separate the cosmogenic helium from noncosmogenic helium (e.g., mantle helium) trapped in the mineral, but several studies have shown convincingly that isotopic analysis of the helium released by cold

Figure 1 High-frequency advances of Mueller Glacier, New Zealand's Southern Alps, reconstructed by high-sensitivity ^{10}Be dating of moraine boulders, including five distinct advances during the last millennium. After Schaefer et al. (2009).

crushing and subsequent analysis of the remaining helium released by heating allows accurate determination of the cosmogenic ^3He concentration (Kurz and Brook, 1994; Niedermann, 2002 and references therein).

^3He from Fe/Ti-oxide minerals and garnet

In 2002, Bryce and Farley (2002) presented cosmogenic ^3He data from magnetite at the Goldschmidt Conference in Davos. Subsequently, Kober et al. (2005) presented a convincing cosmogenic ^3He dataset from Fe/Ti-oxide minerals. Using the ^{21}Ne exposure ages from quartz from the same surfaces, they calibrated the production rate on five different samples (Table 1), resulting in much higher production rates from Fe/Ti-oxide minerals than previously suggested (Bryce and Farley, 2002; Margerison et al., 2005). Kober et al. (2005) also modeled the ^3He production rates from the main target elements (i.e., O, Mg, Al, Si, Fe, Ni; Table 1) and reported excellent agreement between experimentally

and theoretically derived values. The main findings were the high production-rate values from O, Mg, and Al, indicating that elemental analysis for each sample is a requirement for all cosmogenic ^3He studies. This has not been done routinely since cosmogenic ^3He was assumed to be produced at very similar rates to the main target elements given above. Although the discussion about the production rate of cosmogenic ^3He in Fe/Ti-minerals remains controversial for now, this new tool is very promising.

Gayer et al. (2004) reported cosmogenic ^3He data from Himalayan garnets and compared those with ^{10}Be data from coexisting quartz. Their ^3He production-rate calibration results show a trend towards higher $^3\text{He}/^{10}\text{Be}$ production ratio with increasing altitude, which they interpret as an altitude dependence of this production ratio. While certainly more studies are needed to answer the question of element-dependent scaling factors, this study introduces cosmogenic ^3He from garnet as a new SED tool.

Table 1 Recently published TCN production rates at the Earth's surface at SLHL

<i>Path–target–nuclide</i>	<i>Method</i>	<i>Production rate (g⁻¹ year⁻¹)</i>	<i>Reference</i>	<i>Comment</i>
Helium				
S–(Fe/Ti-oxide)– ³ He	Cross-calibrated from cosmogenic ²¹ Ne in coexisting quartz	120 ± 11	Kober et al. (2005)	Valid for present-day magnetic field

In situ ¹⁴C				
S–(quartz)– ¹⁴ C	17.4 ± 0.3 ka	15.1 ± 0.2 16.3 ± 0.2	Lifton et al. (2001), Miller et al., 2006), Lifton et al. (ms in prep.)	Assumes 100% spallation production Assumes 83% spallation, 2% fast muon, 15% slow muon production

This table is complementary to Table 4 in Gosse and Phillips (2001). 'S' means 'spallation.'

²¹Ne from Quartz, Olivine, Pyroxene, and Sanidine

Cosmogenic neon is a more complex system but has specific potential compared to cosmogenic helium. The production rate of cosmogenic ²¹Ne (²¹Ne is preferred over other Ne isotopes because it has the lowest isotopic abundance in air) is less well calibrated, primarily relying on the studies by Niedermann and Graf (Balco and Shuster, 2009; Niedermann, 2000; Niedermann et al., 1994). However, the useful age range is the largest of all TCNs, ranging from 10 ka (Niedermann et al., 1994) to more than 30 Ma (Dunai et al., 2005).

Traditionally, cosmogenic ²¹Ne has been analyzed from quartz (Niedermann et al., 1994), olivine (Poreda and Cerling, 1992), and pyroxene (e.g., Bruno et al., 1997).

²¹Ne from sanidine

Kober et al. (2005) reported successful measurement of ²¹Ne from sanidine (for production-rate values see Table 1) showing that cosmogenic ²¹Ne is quantitatively retained in sanidine. A very interesting aspect of this work is the apparently pure two-component mixture of atmospheric and cosmogenic neon

for all samples analyzed. If nucleogenic neon is less abundant or absent in sanidine, implying that the separation of cosmogenic neon from the neon fraction trapped in the mineral lattice (mostly nucleogenic neon) is not required, cosmogenic neon in sanidine allows for dating of young surfaces. For all studies, analysis of the elemental composition of the mineral separates is required because of large differences between elemental production rates (Table 1). Several elemental production rates rely on modeling so far, which is an additional uncertainty. The analytical measurement of cosmogenic neon is challenging because of doubly-charged ions (e.g., $^{40}\text{Ar}^{++}$, CO_2^{++}) interfering with the single-charged neon isotopes in the collector of the mass spectrometer, which might explain the relatively small number of published cosmogenic neon studies.

^{38}Ar from Calcium

Cosmogenic ^{38}Ar is produced in terrestrial surface rocks by spallation of target nuclides, in particular K and Ca. Though the presence of cosmogenic argon in Ca-rich minerals has been demonstrated earlier (Renne et al., 2001), it has proven difficult to establish its production rate because of problems connected to ^{36}Ar production by ^{35}Cl neutron capture and different production rates from K and Ca. A strategy to circumvent this problem is to analyze essentially Cl- and K-free minerals, as done by Niedermann et al. (2007) using pyroxene, which is low in potassium (Table 1). Although this methodology is still in the developmental stage, calibrating the ^{38}Ar SED method is important because it would allow the use of the many existing Ar/Ar mass spectrometers for this SED technique.

^{10}Be from Calcite, and Sanidine

^{10}Be from calcite

Braucher et al. (2005) report a first attempt to measure *in situ* ^{10}Be from calcite. By comparing the *in situ* ^{10}Be –*in situ* ^{36}Cl concentrations from a depth profile in carbonate rocks, they find constant $^{10}\text{Be}/^{36}\text{Cl}$ ratios for all samples, which suggests that all ^{10}Be was produced *in situ*. They determine a sixfold higher ^{10}Be production rate from calcite than from quartz (see Table 1). In their study, they also report that simple rinsing in deionized water over 24 h removes the meteoric ^{10}Be completely, implying that meteoric ^{10}Be does not adsorb on carbonates. Simple *in situ* ^{10}Be measurements from carbonates would represent a significant advance, particularly interesting for ^{10}Be – ^{36}Cl burial dating techniques. However, as the authors state themselves, “it is a first attempt that must be verified in future studies.”

^{10}Be from sanidine

In addition to the noble gas measurements mentioned above, Kober et al. (2005) measured the ^{10}Be from sanidine following a chemical extraction procedure similar to that routinely done for ^{10}Be from quartz. Again, the production is element-dependent, that is, the elemental composition of each mineral separate has to be measured.

^{26}Al from Quartz

^{26}Al is produced in quartz at a rate approximately 6.8 times higher than that of ^{10}Be (Nishiizumi et al., 1989). *In situ* ^{26}Al and ^{10}Be can be extracted in parallel from the same quartz separate without any significant extra effort during the chemical processing, resulting in a large number of combined ^{26}Al and ^{10}Be studies. The ^{26}Al production rate is nearly as well known as the ^{10}Be production rate. Its useful age range is from a few 1000 years to 2.5 My. The analytical uncertainty is higher than for the ^{10}Be , typically some 5–7%. Another methodological problem is the need for extremely pure, essentially Al-free quartz separates (only 0.5% of feldspar in the quartz separate compromises the ^{26}Al analysis). Its most important recent application is arguably the burial dating technique discussed elsewhere in this encyclopedia.

In Situ ^{14}C from Quartz and Olivine

Over the last decade, the AMS group at the University of Arizona has developed a revolutionary tool – *in situ* ^{14}C . Lifton et al. (2001) report successful routine measurements of *in situ* ^{14}C from quartz. The major challenge, namely, the separation of the atmospheric ^{14}C from the *in situ* ^{14}C , is overcome by a combination of acid etching and stepwise combustion with a degassed oxidizing flux. The major advantage of this new tool is its dating range covering the Holocene, where traditional TCN methods become problematic (with the exception of ^{10}Be see above).

Recent studies combine *in situ* ^{14}C with ^{10}Be SED (Goehring et al., 2011; Miller et al., 2006), introducing pro- and subglacial bedrock as climate and glaciologic archives. This new line of research has a lot of potential, but there are still only a handful of laboratories worldwide equipped with an *in situ* ^{14}C extraction system; also, *in situ* ^{14}C sample processing remains complex, slow, and expensive. However, the Arizona group recently automated the major steps in the extraction process, potentially enabling a fourfold increase in throughput when complete. Work to fine-tune the automation equipment and procedures is ongoing.

An additional application of *in situ* ^{14}C forms one of the core components of the CRONUS-Earth initiative (Figure 2). After about 4–5 half-lives, the production and the decay of *in situ* radionuclides reach secular equilibrium. Therefore, surfaces older than approximately 25 ka can be used to estimate the local ^{14}C production rate since the nuclide inventory under those conditions is only a function of the production rate and the decay constant ($t_{1/2}$ for ^{14}C is 5.73 ka). Doing so along transects in altitude and latitude allows one to constrain time-integrated scaling factors.

^{14}C from olivine

Recently, Pigati et al. (2010) have demonstrated a method for extracting *in situ* ^{14}C from olivine separates, extending the *in situ* ^{14}C method to mafic lithologies. They take an approach similar to that of Lifton et al. (2001), in that they use chemical pretreatments followed by stepped combustion with an oxidizing flux. However, recovery of *in situ* ^{14}C with this method is dependent on the Mg:Fe ratio of the olivine, apparently resulting from chemical interactions in the melted flux. A large

Figure 2 Map of the *in situ* ^{14}C survey within the CRONUS-Earth project.

empirical correction based on this ratio, however, brings the recovered *in situ* ^{14}C concentrations into agreement with *in situ* ^{14}C measurements in quartz samples from similar locations. As with several other methods described here, this is an emerging technique that needs to be verified in future studies.

^{36}Cl from Whole Rock and Feldspar
